Homoacetogens

Definition

Acetogens are defined as anaerobic prokaryotes that use the acetyl-CoA pathway for the (a) reductive synthesis of the acetyl moiety of acetyl-CoA from CO₂, (b) conservation of energy, and (c) assimilation of CO₂ into biomass.

Introduction

Acetogens utilize the acetyl-CoA “Wood–Ljungdahl” pathway as a terminal electron-accepting, energy-conserving, CO₂-fixing process. The reductive synthesis of acetate from CO₂ differentiates acetogens from organisms that synthesize acetate by other metabolic processes. Although the production of acetate as a sole reduced end product is the classic hallmark of acetogens, the production of acetate is not a part of the definition, because the acetogen might not form acetate in situ or when cultured in the laboratory.

The first acetogen, *Clostridium aceticum*, was isolated from soil by the Dutch microbiologist K. T. Wieringa in 1936. This spore-forming, mesophilic bacterium was shown to grow at the expense of H₂–CO₂ and synthesizes acetate according to the following stoichiometry (Wieringa, 1939–1940):

In 1936, this reaction constituted a unique mechanism for the fixation of CO₂. Unfortunately, the culture of

C. aceticum was lost and no further work was done until it was re-isolated in the early 1980s (Braun et al., 1981). In 1942, F. E. Fontaine and coworkers isolated the second acetogen, *Clostridium thermoaceticum* (later reclassified as *Moorella thermoacetica*), a spore-forming, thermophilic bacterium that catalyzed the near stoichiometric conversion of glucose to acetate (Fontaine et al., 1942):

C. thermoaceticum became the most extensively studied acetogen and was used to resolve the enzymology of the acetyl-CoA pathway in the laboratories of two biochemists, H. G. Wood and L. G. Ljungdahl (Drake and Daniel, 2004).

The demonstration that ¹⁴CO₂ was incorporated equally into both carbons of acetate by *C. thermoaceticum* was the first ¹⁴C-study in biology (Barker and Kamen, 1945). The synthesis of acetate from two molecules of CO₂ was later confirmed by Wood using ¹³CO₂ and mass spectrometry (Wood, 1952). Both studies demonstrated that acetogens featured a new autotrophic mechanism for the fixation of CO₂. The acetyl-CoA pathway, also referred to as the Wood–Ljungdahl pathway, is now recognized as a fundamental component of the global carbon cycle, important to primary production in subsurface-ecosystems, and essential to the metabolic potentials of not only acetogens but also methanogens, sulfate-reducers, and anammox bacteria (Wood and Ljungdahl, 1991; Drake, 1994; Schouten et al., 2004).

The acetyl-CoA Wood–Ljungdahl pathway

The acetyl-CoA pathway is a reductive, linear, “one-carbon” process (Figure 1) in contrast to cyclic CO₂-fixing processes (Calvin cycle, reductive tricarboxylic acid cycle, and hydroxypropionate cycle). The two branches of the acetyl-CoA pathway merge at the synthesis of acetyl-CoA that is converted to either acetate or

Acetogens, Figure 1 The acetyl-CoA “Wood-Ljungdahl” pathway. H_4F , tetrahydrofolate; HSCoA , coenzyme A; P_i , inorganic phosphate; e^- , electron; co-protein, corrinoid enzyme; ATP, adenosine-5'-triphosphate. The pathway is from Müller et al. (2004) and used with kind permission of Horizon Bioscience.

assimilated into biomass (Drake, 1994; Drake et al., 2006). Acetyl-CoA synthase (ACS) not only catalyzes the reduction of CO_2 to CO and the synthesis of acetyl-CoA but also oxidizes CO to CO_2 . Thus, the acetyl-CoA synthase is also termed CO dehydrogenase (CODH). Energy conservation occurs during the reductive synthesis of acetate by substrate-level phosphorylation and chemiosmotic processes. For each glucose that is converted to three acetates, four molecules of ATP are produced by substrate-level phosphorylation (ATP_{SLP}). However, when growth occurs under autotrophic conditions, there is no net gain in ATP_{SLP} and growth is dependent upon translocation of protons or sodium ions.

The relatively simple features of the linear acetyl-CoA pathway and the fact that metals and metal sulfides do the biochemical work of CO_2 fixation in the key enzymes of the pathway (i.e., CODH and ACS) suggest that the acetyl-CoA pathway might have been the first autotrophic and early respiratory process on earth and, thus, important in the evolution of life (Wood, 1991; Miyakawa et al.,

2002; Russel and Martin, 2004). It has been proposed that biochemistry started when marine CO_2 from volcanoes and hydrothermal H_2 met at a hydrothermal vent rich in metal sulfides, where an analogue of the exergonic acetyl-CoA pathway catalyzed the synthesis of organic precursors to fuel primordial biochemical reactions.

Phylogenetic diversity of acetogens

Over 100 acetogenic bacterial species have been isolated to date from very diverse habitats, including marine and freshwater sediments; salt lake soda deposits; tundra, forest, and agricultural soils; the subsurface; fecal material; and marine and salt marsh plants (Drake et al., 2006, 2008). Acetogens display extreme genetic diversity, having genomic G + C contents that vary between 22 mol% (*Clostridium ljungdahli*) to 62 mol% (*Holophaga foetida*). Acetogens have been assigned to 22 different bacterial genera including *Acetivibrio*, *Acetobacterium*, *Acetohalobium*, *Acetonebium*, *Bryantella*, “*Butyrivibrio*,” *Caloramator*, *Clostridium*, *Eubacterium*, *Holophaga*, *Moorella*, *Natroninella*, *Natronincola*, *Oxobacter*, *Ruminococcus*, *Sporomusa*, *Syntrophococcus*, *Tindallia*, *Thermoacetogenium*, *Thermoanaerobacter*, and *Treponema* (the name in quotation marks has not been validated). The diverse habitat range of acetogens demonstrates that they are adapted to a broad range of in situ conditions. Many acetogens are sporeformers (e.g., Byrner et al., 2000), a feature that aids in surviving unfavorable in situ conditions, and some acetogens have connecting filaments (Küsel et al., 2001) that might facilitate communication. The usage of the acetyl-CoA pathway for autotrophic assimilation of carbon and acetate utilization by methanogens suggests that Archaea also can grow via acetogenesis. Indeed, the methanogen *Methanosarcina acetivorans* C2A uses the acetyl-CoA pathway to convert carbon monoxide to both acetate and methane, that is, methane is not the sole reduced end product of this methanogen (Rother and Metcalf, 2004; Lessner et al., 2006). Similarly, the archaea *Archaeoglobus fulgidus* VC16 can grow via CO-dependent acetogenesis (Henstra et al., 2008).

Only some acetogenic genera, like *Moorella* and *Sporomusa*, are monophyletic, but many acetogens are phylogenetically dispersed within genera that contain non-acetogenic species. Thus, the phylogenetic position of 16S rRNA gene sequences is usually inadequate for resolving the functional identity of a potential acetogen. To date, only some highly specific 16S rRNA-based probes and primers have been designed to target subsets of acetogenic taxa (Küsel et al., 1999). Molecular approaches based on the analysis of functional genes central to the acetyl-CoA pathway (e.g., a gene for formyltetrahydrofolate synthetase) are still limited due to problems of probe specificity (Leapheart et al., 2003).

Functional diversity of acetogens

Acetogens utilize a wide variety of electron donors and electron acceptors and can engage alternative terminal

electron-accepting processes when challenged with O_2 (Drake et al., 2006). Many acetogens can utilize one or more terminal electron-accepting processes in addition to acetogenesis. For example, nitrate is a preferred electron acceptor for *M. thermoacetica* and is dissimilated to nitrite and ammonium (Seifritz et al., 1993), and perchlorate is a preferred terminal electron acceptor for *Moorella perchloratireducens* (Balk et al., 2008). The engagement of diverse redox couples enables acetogens to form junction points within and between biological cycles at the ecosystem level (Drake and Küsel, 2005). Acetogens are known to use the following alternative terminal electron acceptors that yield diverse end products listed below:

Fumarate $\rightarrow$ succinate
 Methoxylated phenylacrylates $\rightarrow$ methoxylated phenyl propionates
 Nitrate $\rightarrow$ nitrite
 Nitrite $\rightarrow$ ammonium
 Thiosulfate $\rightarrow$ sulfide
 Dimethylsulfoxide $\rightarrow$ dimethylsulfide
 Perchlorate $\rightarrow$ chloride
 Chlorate $\rightarrow$ chloride
 Pyruvate $\rightarrow$ lactate
 Acetaldehyde $\rightarrow$ ethanol
 Protons $\rightarrow$ hydrogen gas

CO , H_2 , carbohydrates, alcohols, carboxylic acids, dicarboxylic acids, aldehydes, substituent groups of various aromatic compounds, and certain halogenated substrates are examples of substrates that acetogens can oxidize. Although hexoses or pentoses are utilized by most of the acetogens isolated to date, none of these isolates appear to be able to degrade high molecular weight polymers, such as cellulose and lignin. Most acetogens have the capacity to produce more than acetate as their sole reduced end product, and this capacity is dependent on the availability of both reductant and terminal electron acceptors, including CO_2 . Thus, referring to acetogens as homoacetogens is usually a misnomer.

In anoxic habitats, acetogens compete with primary fermentors for monomeric compounds that are derived from the initial breakdown of cellulose and lignin and with secondary fermentors for fermentation products. Thermodynamic considerations suggest that acetogenesis should not be a highly competitive microbial process. Nonetheless, acetogens can outcompete methanogens for H_2 in freshwater sediments with low pH and low temperature and in the hindgut of certain termites (Conrad et al., 1989; Breznak and Kane, 1990; Drake et al., 2006). Microbially produced acetate can provide up to 100% of the energy requirement of wood-feeding termites. The attachment of H_2 -consuming acetogenic spirochetes to H_2 -producing protozoa provides H_2 concentrations above the known H_2 -threshold values for acetogens.

Another ecological advantage might be the low oxygen sensitivity of certain acetogens (Figure 2). Acetogens have been classically referred to as obligate, if not strict, anaerobes, and many enzymes central to acetogenesis are

Acetogens, Figure 2 Mechanisms by which acetogens cope with oxidative stress. X, products (e.g., H_2 , formate, lactate) that are derived from the partial oxidation of carbohydrates (in some cases, short-chain polymers [e.g., stachyose] that are not substrates for the acetogen); e^- , electron. (Modified from Müller et al., 2004, and used with kind permission from Horizon Bioscience.)

extremely sensitive to O_2 . However, acetogens have been isolated from oxic habitats, like soils and the rhizosphere of macrophytes that release O_2 through their roots, indicating that such acetogenic species must cope with periods of oxidative stress. Acetogens contain numerous enzymes that can reductively remove O_2 and its toxic by-products (e.g., superoxide and peroxide), when the concentration of O_2 is relatively low (Drake et al., 2006). These enzymes include peroxidase, NADH-oxidase, rubredoxin oxidoreductase (a superoxide reductase), rubrerythrin (a peroxidase), superoxide dismutase, catalase, and cytochrome *bd* oxidase (Das et al., 2001, 2005; Küsel et al., 2001). Acetogens can shift the flow of reductant away from the acetyl-CoA pathway to alternative terminal electron-accepting processes that are less sensitive to O_2 and operate at higher redox potentials than the very low standard redox potential of the CO_2 /acetate half-cell reaction (-290 mV). For example, *Clostridium glycolicum* RD-1 (isolated from seagrass roots) is an aerotolerant acetogen that switches from acetogenesis to

classic fermentation in response to O₂ (Küsel et al., 2001). Acetogens can also form symbiotic relationships with O₂-consuming microaerophiles and aerotolerant fermenters (Göbner et al., 1999). The microaerophile can be a fermentative non-acetogen that has the capacity to consume O₂ and forms fermentation products (e.g., lactate, formate, and H₂) that can be used by the acetogen for acetogenesis. Such interactions can protect acetogens from oxidative stress and form trophic linkages in habitats with fluctuating redox conditions.

Conclusions

It has been estimated that approximately 10¹² kg of acetate is synthesized per year via H₂-driven acetogenesis in sediments and the hindgut of termites (Breznak and Kane, 1990), a number that is fivefold greater than the annual amount of methane produced via the methanogenic reduction of CO₂. Such estimates accentuate the potential importance of acetogens and acetogenesis to the global carbon cycle. However, in situ acetate turnover measurements are complicated and acetogens catalyze a large number of redox reactions, suggesting that their in situ activities are not restricted to acetogenesis. Thus, although acetate forms an important trophic link in a wide variety of ecosystems, in situ information on acetogens and their activities are often theoretical.

ACID ROCK DRAINAGE

Lesley A. Warren
 McMaster University, Hamilton, ON, Canada

Synonyms

Acid mine drainage; AMD; ARD

Definition

Acid mine and acid rock drainage (AMD/ARD) refer to the extremely acidic ($pH < 3$), metal-rich waters that are derived from the weathering of sulfidic minerals when exposed to air, water, and microorganisms ([Figure 1](#); Nordstrom and Alpers, 1999; Bond et al., 2000):

Acid Rock Drainage, Figure 1 An AMD stream at a nickel-copper mine in northern Ontario, Canada. The orange and red colours in the stream are Fe-oxyhydroxide and Fe-sulphate mineral precipitates.

Environmental significance

AMD/ARD is considered to be the most important and widespread global-mining-industry-related pollution problem (Rowe et al., 2007). The main characteristics of ARD/AMD are (1) low pH, (2) high concentrations of dissolved heavy metals, and (3) high concentrations of sulfate (SO_4^{2-} , Tsukanoto et al., 2004). Total dissolved metal concentrations as high as 200,000 mg/L and dissolved SO_4^{2-} as high as 760,000 mg/L have been reported to be associated with AMD (Nordstrom et al., 2000).

AMD/ARD generation

AMD is generated through a combination of chemical and biological (microorganism) processes by which sulfidic minerals are converted to sulfates and iron oxyhydroxides

ACID ROCK DRAINAGE

Lesley A. Warren
 McMaster University, Hamilton, ON, Canada

Synonyms

Acid mine drainage; AMD; ARD

Definition

Acid mine and acid rock drainage (AMD/ARD) refer to the extremely acidic (pH < 3), metal-rich waters that are derived from the weathering of sulfidic minerals when exposed to air, water, and microorganisms ([Figure 1](#); Nordstrom and Alpers, [1999](#); Bond et al., [2000](#)):

Environmental significance

AMD/ARD is considered to be the most important and widespread global-mining-industry-related pollution problem (Rowe et al., [2007](#)). The main characteristics of ARD/AMD are (1) low pH, (2) high concentrations of dissolved heavy metals, and (3) high concentrations of sulfate (SO₄²⁻, Tsukanoto et al., [2004](#)). Total dissolved metal concentrations as high as 200,000 mg/L and dissolved SO₄²⁻ as high as 760,000 mg/L have been reported to be associated with AMD (Nordstrom et al., [2000](#)).

AMD/ARD generation

AMD is generated through a combination of chemical and biological (microorganism) processes by which sulfidic minerals are converted to sulfates and iron oxyhydroxides

when exposed to water and oxygen (see [Sulfide Mineral Oxidation](#)). The overall oxidative dissolution of pyrite (FeS_2), a widespread common mine constituent, and associated with AMD generation is given by [Equation 1](#):

This process progressively increases water acidity, resulting in the mobilization of metals from mine wastes. AMD generation is typically amplified when the reactions involved in the overall process, described in [Equation 1](#), are catalyzed by aerobic Fe- and S-oxidizing bacteria, such as *Acidithiobacilli* (formerly *Thiobacilli*, e.g., *Acidithiobacillus ferrooxidans*; see [Biomining \(Mineral Bioleaching, Mineral Biooxidation\)](#); [Sulfide Mineral Oxidation](#)). However, factors such as levels of microorganism activity, pH, sulfide mineral area, crystallography, type of sulfide mineral, temperature, and oxygen concentration all interactively influence the rate of AMD generation (Berghorn and Hunzeker, 2001).

[Figure 2](#) provides a schematic illustrating the overall AMD generation process. Initiation at neutral pH occurs through the release of ferrous iron (Fe^{2+}) and acid (H^+) into solution ([Equation 2](#)):

At pH values <4 , increased solubility of ferric iron promotes Fe^{3+} pyrite oxidation ([Equation 3](#)) at far greater rates than those associated with O_2 oxidation:

At pH values greater than 4, O_2 -driven oxidation of ferrous iron to ferric iron ([Equation 4](#)) results in Fe oxyhydroxide formation ([Equation 5](#)) and iron removal through precipitation:

In addition, as the pH decreases below 4, iron-oxidizing bacteria, many of which are adapted to pH values of 2–4, substantively increase rates of Fe oxidation ([Equation 4](#)) by factors greater than 10^6 . For these reasons, the oxidation of Fe^{2+} to Fe^{3+} is often referred to as the rate-determining step in the acid generation process. Thus, once the system reaches pH values less than 4, a self-perpetuating cycle of Fe^{3+} -driven oxidation of pyrite and regeneration of Fe^{3+} through Fe oxidizers is initiated, producing more acidity and Fe^{2+} until either ferric iron or the pyrite waste is depleted ([Figure 2](#)).

Acid Rock Drainage, Figure 2 A schematic of AMD generation based on FeS_2 , indicating the relative importance of O_2 vs Fe^{3+} -driven oxidation rates and the role of microorganisms as a function of pH. At low pH, Fe^{3+} -driven pyrite oxidation releases greater acidity than O_2 -driven pyrite oxidation, which is more favourable at circumneutral pH values.

Treatment of acid mine drainage

AMD waters must be treated to remove metals and raise the pH before they are discharged to a receiving environment (Neculita et al., 2007). Numerous approaches, often characterized as active or passive, exist to treat AMD. Active processes refer to operations that require a relatively high degree of management and continuous input of consumables, while passive processes theoretically require minimal management and other costs once they are established (Johnson, 2006). The most widespread method is active treatment involving the addition of a chemical neutralizing agent or base (i.e., lime or Ca oxide, CaCO_3 , Na/Mg carbonates, Na/Mg hydroxides) to increase water pH and precipitate metals as hydroxides and carbonates. Over the last 20 years, there have been considerable new developments for AMD treatment including constructed wetlands (Johnson and Hallberg, 2002), bioreactors, and permeable reactive barriers (Blowes et al., 2000), which take advantage of the increasing knowledge of microbially driven reactions. Much of the biotechnology developments rely on sulfate-reducing bacteria (SRB) to treat AMD. Fundamentally, bioreactors use SRB to drive sulfide precipitation, removing metals from the AMD solution (Equations 6 and 7):

where M^{Z+} is a cationic metal such as Cu or Ni.

In addition, SRB will drive alkalinity generation (Equation 6) (Koschorreck and Tittel, 2007). However, all emerging treatment approaches are challenged with regard to long-term efficiency. In large part, this reflects the challenges in identifying the complex and dynamic reactions involved in the overall AMD process. The exact mechanisms and controls involved in reactions as well as an understanding and identification of the microbial flora required to efficiently drive desired reactions for bioreactors over the long-term have not yet been elucidated (Edwards et al., 2000; Bernier and Warren, 2005; Bernier and Warren, 2007). In particular, growing evidence of the importance of consortia or mixed microorganism communities in driving AMD-associated processes underscores the need to more fully investigate the interactive roles of bacteria, system pH, $[\text{Fe}]$, $[\text{O}_2]$, and other [metals] involved in the process to narrow the gap in determining effective long-term strategies to mitigate AMD.

Summary

AMD/ARD refer to metal-rich acidic waters that are generated through the exposure of sulfidic minerals in mine wastes to water, oxygen, and microorganisms. These discharges are a significant global pollution issue associated with mining activities. Both sulfur- and iron-oxidizing bacteria are involved with Fe-oxidizing bacteria playing a key role in the increased rates of AMD generation compared to abiotic (nonbiologically stimulated oxidation) sulfidic wastes. AMD must be treated for the high levels of acidity and metals before it can be released to the

environment. New treatment strategies are emerging that include some combination of chemical and biological approaches; however, all are challenged with regard to long-term efficacy. New research evaluating the roles of environmentally mixed communities of microorganisms demonstrates the opportunities to harness environmentally occurring microorganisms to combat AMD.

ACIDOPHILES

“Acidophiles” are organisms thriving in environments below pH 5. For details, see entries “*Extreme Environments*,” “*Biomining (Mineral Bioleaching, Mineral Biooxidation)*,” “*Hot Springs and Geysers*,” *Hydrothermal Environments (Marine)* and “*Acid Rock Drainage*.”

ACRITARCHS

Acritarchs are organic-walled acid-resistant microfossils known from the Proterozoic and throughout the Phanerozoic. The position of these microfossils is still uncertain. A number of acritarch genera have been assigned to Green Algae; others are considered to bear some resemblance to the cysts of dinoflagellates. For more information, please refer to entries “Algae, Eukaryotic” and “Protozoa.”

AEROBIC METABOLISM

Heribert Cypionka
University of Oldenburg, Oldenburg, Germany

Synonyms

Aerobic respiration; Oxygen metabolism

Definition

Aerobic metabolism comprises the reduction of molecular oxygen as electron acceptor of aerobic respiration, its use as cosubstrate in the degradation of certain compounds, and reactions leading to the detoxification of partially reduced oxygen species.

Introduction

Life has evolved in the absence of molecular oxygen (see Chapter *Early Earth*). Therefore, it is not surprising that basic metabolic pathways involved in growth and cell division (like DNA replication or protein synthesis) do not depend on the presence of molecular O₂. The evolution of the oxygen-producing (oxygenic) phototrophs dramatically changed the situation of living organisms. Molecular oxygen raised the redox potential of the environment and enabled microorganisms to respire with a much higher energy yield than before. Although oxygen is involved in

a limited number of reactions only, its presence or absence has fundamental impact on biogeochemical processes.

Aerobic degradation of organic matter

Aerobic respiration consumes a major part of the photosynthetically produced O₂ and about 90% of the organic matter (see Chapter *Carbon Cycle*). Aerobic (oxygen-metabolizing) organisms normally oxidize their substrates completely to CO₂. In most cases, O₂ is not directly involved in this process. Substrate oxidation generates reduced electron carriers by means of the respiratory chain. Oxygen is reduced as the last step of the respiration process.

Respiratory chain

Respiration is a membrane-bound process that generates a chemiosmotic proton gradient across the membrane (Mitchell, 1966). Respiratory chains are composed of series of enzymes, which are organized in multienzyme complexes and use cofactors that allow the stepwise transport of reducing equivalents to oxygen (Figure 1). In eukaryotes (plants, animals, fungi) it takes place within the mitochondria, which are assumed to have evolved from endosymbiotic bacteria. In prokaryotes (Bacteria, Archaea), the respiratory chain is located in the cytoplasmic membrane. The respiratory chain of the bacterium *Paracoccus denitrificans* appears to have many similarities to the mitochondrial type (Harold, 1986). However, many bacteria have variations compared to the mitochondrial type presented in Figure 1.

Energetics and ATP conservation

Most reducing equivalents are fed into the respiration process via NADH₂, which has a standard redox potential (E_0') of -0.32 V. The terminal electron-accepting redox pair O₂/H₂O has redox potential of $+0.82$ V. Thus, the usable redox potential is about 1.14 V. From this redox potential one can calculate a standard $\Delta G_0'$ of -440 kJ per mol of O₂. Assuming that ATP conservation requires about -75 kJ per mol, the conservation of 5 to 6 ATP per O₂ reduced is possible. As a consequence of the high ATP yield, aerobic organisms can form more biomass from the same amount of substrate than anaerobic organisms.

Use of oxygen as cosubstrate

Molecular oxygen is used as a cosubstrate in some catabolic and anabolic reactions (Lengeler et al., 1999). The enzymes involved are called mono- or di-oxygenases, depending on the number of oxygen atoms transferred to their substrate. Oxygenases are used by aerobes to activate certain substrates that do not have functional groups that allow a simple degradation. They catalyze the initial hydroxylation of hydrocarbons to yield alcohols that can easily be metabolized further. They are also involved in the ring cleavage of aromatic compounds and in the first oxidation step of ammonia oxydation. Anaerobic organisms are either unable to oxidize the substrates activated

ANIMAL SKELETONS, ADVENT

Guoxiang Li, Maoyan Zhu, Zhe Chen
 Chinese Academy of Sciences, Nanjing, China

Synonyms

Early biomineralization event; Small shelly fossils

Definition

Animal skeleton. Biologically, an animal skeleton is a hard or rigid framework that could provide protection and

support in many types of animals. Most of the animal skeletons are mineralized, but some of them may not be mineralized (e.g., some annelid tubes being agglutinated). They could be subdivided into exoskeletons and endoskeletons, excluding hydroskeletons. The “skeletons” of resistant organic biopolymers are not included herein.

Exoskeleton. Exoskeletons are external hard parts. They may enclose the soft tissues and organs of the body, or may be external sclerites.

Endoskeleton. Endoskeletons are internal hard parts (typical of many vertebrates). Most of the endoskeletons are generally surrounded by skin and musculature.

Small shelly fossils (SSF or SSFs). A non-taxonomic term was first used by Matthews and Missarzhevsky in the title of their review paper in 1975 to denote the earliest skeletal fossils, although some of these fossils may not be small and most of them are actually not shells. It has been popularly used in literature somewhat as a catchall term for the early Cambrian skeletal fossils, including spicules, shells, tubes, and diverse disarticulated sclerites.

Introduction

Skeletal biomineralization (skeletonization) was part of the initial diversification of early animals. The fossil record provides an important clue to the origin of biomineralization in the animal phyla (Kirschvink and Hagadorn, 2000). The earliest occurrence of animal skeletons was in the late Ediacaran, e.g., *Cloudina*, *Sinotubulites*, and *Namapoikia*, although the generic diversity was quite low and the biomineralization of these calcareous skeletons was not well controlled biologically (Grant, 1990). The early Cambrian (542–525 Ma) saw the largest burst of diversified animal skeletons, represented in the fossil record by poriferans, cnidarians, many extant bilaterian phyla, and some problematic taxa (Figure 1) (Bengtson, 2004). In terms of structural and mineralogical diversity of animal skeletons, the early Cambrian represents a quantum jump (Bengtson and Conway Morris, 1992). The abrupt advent of diversified skeletal fossils not only has been taken as a major piece of evidence for the Cambrian radiation but also was envisioned the biomineralization event. Since most of these skeletal fossils are typically small in size, and lots of them represent disarticulated sclerites and are enigmatic with respect to their biological affinities, they are commonly referred to as “small shelly fossils (SSFs)” in the literature (Matthews and Missarzhevsky, 1975; Qian, 1999). But some of the early skeletal fossils, such as the sponge-like archaeocyaths, trilobites, and bivalved arthropods, are rarely described under this nontaxonomic term, while some fossils described under the term of SSFs, such as embryo fossils and cnidarian polyps, may have been originally composed of resistant organic membranes or tubes without biomineralization, and the skeleton-like appearance is mainly due to the secondary phosphatization.

Animal Skeletons, Advent, Figure 1 Distribution of major skeletal animal taxa (biomineralized and agglutinated) from the late Ediacaran to the early Cambrian.

Mineralogy of early animal skeletons

Animals use a variety of minerals to fabricate their skeletons (Lowenstam and Weiner, 1989). However, there are only three principal classes of minerals being widely used by organisms, including calcium carbonates, calcium phosphates, and silica. Calcium, carbonate, and phosphate ions are abundant in the oceans, and are ready for use in skeletons (Kirschvink and Hagadorn, 2000), despite

skeletogenesis being a biologically controlled, complex process. Animals rarely switched their mineralogy after their first skeletogenesis, indicating that, for most lineages, environment does not strongly influence skeleton composition, although the selection of skeletal mineralogy during the first acquisition of skeletons in a clade may be somewhat related to ambient seawater chemistry (Knoll, 2003; Porter, 2007; Zhuravlev and Wood, 2008).

It is in most cases not apparent to identify the original minerals of early fossil skeletons because of diagenetic alterations. Especially, there was a very significant phosphogenic event around the Ediacaran-Cambrian transition (Cook and Shergold, 1984), and thus secondary phosphatization of early skeletal fossils was quite common (Qian and Bengtson, 1989). The original composition of fossil skeletons can be learnt by inference and comparative analysis. The fossil record shows that early animals mainly used calcium carbonates, apatites, and silica to build their skeletons (Figure 1).

Several polymorphs of calcium carbonates are the major skeleton-forming minerals, including calcite (high-Mg calcite, low-Mg calcite), aragonite, and vaterite. Vaterite is an extremely unstable polymorph of CaCO_3 and is rarely used as a biomineral. Aragonite is an unstable mineral and it is easily transformed to low-Mg calcite during diagenesis; hence, the original mineralogy of early calcareous fossils is difficult to identify in many cases (Bengtson and Conway Morris, 1992). The earliest animal skeletons during the late Ediacaran-Tommotian interval were composed exclusively of aragonite and high-Mg calcite, being consistent with an aragonite sea (Porter, 2007; Zhuravlev and Wood, 2008). Since the early Atdabanian, there occurred many clades of animals using low-Mg calcite to make skeletons, implying the onset of a calcite sea.

Apatite is another major mineral for early animals to make skeletons (Figure 1), and it is diagenetically the most stable among the major skeleton-building minerals (Bengtson and Conway Morris, 1992). Phosphatic skeletons are usually a combination of phosphate and organic material and hence are called organo-phosphatic. Comparative study indicates that phosphatic skeletons in the

earliest metazoans appear to have been more widespread than today (Runnegar and Bengtson, 1990). The early phosphatic skeletal metazoans include brachiopods (Linguliformea), cnidarians (hyolithelminths, byroniids, and conulariids), bradoriids, lobopodian, protoconodonts, and conodont-like fossils, tomotiids, etc. The high diversity of phosphatic skeletons is somewhat related to wide distribution of phosphate deposits (phosphogenesis event) in various parts of the world during the early Cambrian (Cook and Shergold, 1984).

Siliceous (opal) skeletons differ in distribution from those made of CaCO_3 since silica biomineralization is limited to intracellular precipitation. Therefore, in animals, siliceous skeletons are limited to sponge spicules and other minor occurrences (Bengtson and Conway Morris, 1992). Opal has been used by sponges (including Demospongia and Hexactinellida) to build their skeletons since the late Ediacaran (Gehling and Rigby, 1996). Biogenic opal is unstable and it usually recrystallizes to quartz during diagenesis.

Agglutinated conchs are occasionally found in the Lower Cambrian rocks such as *Salterella*, *Volborthella*, and *Platysolenites*. Both *Salterella* and *Volborthella* are metazoans (Yochelson and Kisselev, 2003), but their biological affinities are uncertain. They have a calcareous sheath partially filled with detrital grains, agglutinating into laminations. *Platysolenites* represents an agglutinating foraminiferan (Glaessner, 1963).

Morphological variety of early animal skeletons

The morpho-types of the animal skeletons in the late Ediacaran are relatively few. They are mainly represented by weakly mineralized calcareous tubes (e.g., *Cloudina*,

Animal Skeletons, Advent, Figure 2 Examples of late Ediacaran skeletal fossils. (a, b) *Cloudina*, an enigmatic tubular fossil, possibly related to annelids; (c, d) *Sinotubulites*, a tubular fossil of unknown affinity. All from the Dengying Formation in southern Shaanxi, China. Scale bars = 500 μm .

Scale bars = 100 μm , except in j2 = 500 μm .

Sinotubulites) (Figure 2) (Hua et al., 2005), modular skeletons (e.g., *Namapoikia*) (Wood et al., 2002), sponge spicules (Brasier et al., 1997) or a reticulating net of spicules (e.g., *Paleophragmodictya*) (Gehling and Rigby, 1996), and goblet-shaped *Namacalathus* (Grotzinger et al., 2000).

Various types of the animal skeletons abruptly occurred in the early Cambrian. Using the theoretical “Skeleton Space” concept, Thomas et al. (2000) made an analysis of Cambrian animal skeletons. Their analysis showed that about 50% of skeletal design elements recognized among living and extinct marine metazoans were exploited in the early Cambrian (Tommotian) and about 80% exploited in the middle Cambrian Burgess Shale animals. The early Cambrian animal skeletons include univalved (Figure 4d, i, n) and bivalved shells (Figure 4e, f), arthropod carapaces (Figure 4g, h), diverse tubes (Figure 4a–c, l), spicules, diverse external sclerites (Figure 3), tooth-like structures (Figure 3c–e), calcareous massive reinforcements (e.g., archeocyathans), echinoderm ossicles, etc.

Late Ediacaran skeletal metazoans

Prior to the Cambrian, the evidence for animal life was almost the soft-bodied Ediacaran fauna and the advent of skeletal animals had been considered to be in the lowermost Cambrian until Germs (1972) described the first Precambrian skeletal fossil *Cloudina* from the Nama Group in Namibia. Since then, biomineralized fossil assemblages have been widely found in the latest Ediacaran over the world, although the biodiversity is very low. Up to now, there are only several skeletal fossil genera being discovered from the Upper Ediacaran rocks, including *Cloudina*, *Sinotubulites*, *Namapoikia*, *Namacalathus*, and *Paleophragmodictya*. Most genera became extinct at the base of the Cambrian, suggesting that a mass extinction occurred at the latest Ediacaran (Amthor et al., 2003).

The worldwide distributed *Cloudina* is a calcareous conical fossil consisting of funnel-like, apically flaring cones nested with one another (Figure 2a, b). The zoological affinities of *Cloudina* are uncertain, but occasional evidence for budding supports either a cnidarian interpretation

Animal Skeletons, Advent, Figure 4 Examples of early Cambrian tube-dwelling and shell-bearing animals. (a) *Torellella*, a tube-like fossil of unknown affinity; (b) *Anabarites*, a tube-like fossil of cnidarian. (c) *Conotheca*, a hyolith; (d) *Aldanella*, a possible gastropod; (e) A ventral valve of *Eohardrotreta*, acrotretid brachiopods; (f) A ventral valve of *Palaeobolus*, lingulid brachiopods; (g) *Dabashanella*, a phosphatocopid; (h) *Kunmingella*, a bradoriid; (i) *Canopoconus*, a possible mollusk; (j) *Hexangulaconularia*, a conulariid (Cnidaria); (k) *Lathamella*, a stem-group brachiopod; (l) *Cupitthea*, a tube-like fossil of unknown affinity; (m) *Watsonella*, a rostroconch (Mollusca); (n) *Archaeospira*, a gastropod. All from the Lower Cambrian of South China (b, c, i, n: After Qian and Bengtson, 1989). Scale bars = 100 μ m.

(Grant, 1990) or an annelid relation (Hua et al., 2005). The *Cloudina* tubes contain the earliest evidence of predatorial borings (Figure 2b). The enigmatic *Sinotubulites* (Figure 2c, d) is a cylindrical fossil, and its tube is composed of several thin layers and characterized by “tube-in-tube” structure (Chen et al., 2007). It has been only documented from the Dengying Formation in South China and co-occurred with *Cloudina*. The irregular wrinkle ornamentation of outer layer shows the *Sinotubulites* tubes being plastic, implying that the tube wall was dominantly organic with aragonitic mineralization (Chen et al., 2007).

Namapoikia is a late Ediacaran, fully biomineralized metazoan from the Nama Group, Namibia, and it is up to 1 m in diameter and bears a complex and robust calcareous skeleton (Wood et al., 2002). It resembles chaetid sponges or simple colonial cnidarians. *Namacalathus* is another calcified animal from the late Ediacaran, and it is goblet shaped up to 2 cm across (Grotzinger et al., 2000). It is more likely to be a cnidarian than a sponge. Both *Namapoikia* and *Namacalathus* co-occur with *Cloudina*.

Hexactinellid sponges have also been found in the late Ediacaran, including the body fossil *Paleophragmodictya*

(with a reticulating net of spicules) (Gehling and Rigby, 1996) as well as clusters of siliceous spicules (Brasier et al., 1997).

Early Cambrian skeletal metazoans

The great watershed in skeletal biomineralization was the early Cambrian, where the diversity of skeletal animals increases nearly exponentially over the interval. Compared with the limited diversity of skeletal fossils in the Ediacaran, the Lower Cambrian is marked by an extraordinary burst of skeletal fossils. Most skeletal metazoans (extant and extinct) appeared for the first time during the early Cambrian (Figure 1). Among these skeletal fossils, many “skeletons” were not integrated and consisted of numerous discrete sclerites, e.g., cambroclaves, tomotiids, halkieriids, cancelloriids, etc. (Figure 3).

Although the advent of animal skeletons in the early Cambrian is quite abrupt or explosive in relation to the long geologic history, the first appearances of different clades in the early Cambrian are sequential (Li et al., 2007). Anabaritids, hyoliths, maikhanellids (mollusks),

and protoconodonts (chaetognaths) first occurred in the early Meishucunian, coeloscleritophorans, tommotiids in the middle Meishucunian, while crown group brachiopods, skeletal arthropods, and lobopods first occurred in the early Qiongzhusian (Figure 1). The skeletal fossil record shows that the clades occurring in the pre-trilobitic interval (Meishucunian) include many extant phyla such as Porifera, Cnidaria, Annelida, Mollusca, Chaetognatha, Brachiopoda (Lingulids), and a number of extinct taxa such as Hyolitha, stem-group brachiopods, tommotiids, coeloscleritophorans, cambroclaves, coleoloids, paracarinachitids, etc. The pre-trilobitic skeletal fossils were dominated by helcionellids (Mollusca), hyoliths, other problematic sclerites, cap-shaped fossils, and tube-like fossils. They are distinctively different from the “Cambrian Evolutionary Fauna,” and were christened the “Tommotian Fauna” (Sepkoski, 1992).

In the Qiongzhusian (Atdabanian) stage, besides many extinct clades, nearly all extant skeletal invertebrate phyla occurred (except Byrozoa with first occurrence in the early Ordovician). The dominant and characteristic skeletal fossils of this interval include arthropods, brachiopods, and echinoderms, representing an initial stage of the “Cambrian Evolutionary Fauna.”

Summary

The earliest skeletal fossils came from the late Ediacaran rocks, but the early Cambrian witnessed the largest burst of animal skeletons. The abrupt advent of diverse skeletal fossils is an important part of the Cambrian explosion, and biomineralization of animal hard parts provides many advantages for metazoan diversification. Although the trigger for this early biomineralization event has been a subject of extensive debate in literature, it should be an integrating result of extrinsic and intrinsic (biological) factors. The fossil record also exhibits that, along with the rapid diversification of metazoans in the early Cambrian, the metazoans progressively exploited more ecological space. Most of the pre-trilobitic skeletal faunas came from the shallow-water deposits, but during the Qiongzhusian, there already existed a distinct differentiation of shallow water and deep water habitats: a strong linkage between the occurrences of the skeletal fossils and sedimentary environments.

ARCHAEA

Volker Thiel
 University of Göttingen, Göttingen, Germany

Synonyms

Archaeobacteria (term abandoned)

Definition

The Archaea are single-celled or filamentous prokaryotes that constitute the third phylogenetic domain of life, besides the Bacteria and the Eukarya. The word “Archaea” (singular archaeum, archaeon) is derived from the Greek word for “the old ones”.

History

The discovery of the Archaea dates back to 1976 when Carl Woese, at his laboratory at Illinois University, compared prokaryotic small subunit ribosomal RNA sequences using oligonucleotide catalogs (Woese, 2007). Woese recognized *Methanobacterium thermoautotrophicum* as the first member of a fundamentally distinct group of prokaryotes that clustered away from all other bacteria. Consequently, Woese and Fox (1977) established the concept of two separate prokaryotic “urkingdoms,” Eubacteria and Archaeobacteria. Later, the term “Archaeobacteria” was changed to “Archaea” to emphasize the fundamental differences between both groups. Based on these discoveries, Woese and his coworkers proposed the now-accepted division of life into the three domains of Archaea, Bacteria, and Eukarya (Figure 1; Woese et al., 1990).

Specific traits

Like the Bacteria, most Archaea show a cell size between 0.5 and 2 μm and lack a cell nucleus, internal membranes, and organelles. However, a number of traits distinguish the Archaea from members of the other domains of life:

1. The genetic machinery of Archaea is different from Bacteria and Eukarya. The distinctive archaeal “signature” contains more than 1,000 archaeal protein-encoding genes. These signature genes account for a significant portion (9–15%) of archaeal genomic DNA (Graham et al., 2000). The archaeal RNA polymerase, an enzyme producing RNA chains from DNA gene templates, consists of eight (methanogens

ACIDOPHILES

“Acidophiles” are organisms thriving in environments below pH 5. For details, see entries “*Extreme Environments*,” “*Biomining (Mineral Bioleaching, Mineral Biooxidation)*,” “*Hot Springs and Geysers*,” *Hydrothermal Environments (Marine)* and “*Acid Rock Drainage*.”

ACRITARCHS

Acritarchs are organic-walled acid-resistant microfossils known from the Proterozoic and throughout the Phanerozoic. The position of these microfossils is still uncertain. A number of acritarch genera have been assigned to Green Algae; others are considered to bear some resemblance to the cysts of dinoflagellates. For more information, please refer to entries “Algae, Eukaryotic” and “Protozoa.”

AEROBIC METABOLISM

Heribert Cypionka
University of Oldenburg, Oldenburg, Germany

Synonyms

Aerobic respiration; Oxygen metabolism

Definition

Aerobic metabolism comprises the reduction of molecular oxygen as electron acceptor of aerobic respiration, its use as cosubstrate in the degradation of certain compounds, and reactions leading to the detoxification of partially reduced oxygen species.

Introduction

Life has evolved in the absence of molecular oxygen (see Chapter *Early Earth*). Therefore, it is not surprising that basic metabolic pathways involved in growth and cell division (like DNA replication or protein synthesis) do not depend on the presence of molecular O₂. The evolution of the oxygen-producing (oxygenic) phototrophs dramatically changed the situation of living organisms. Molecular oxygen raised the redox potential of the environment and enabled microorganisms to respire with a much higher energy yield than before. Although oxygen is involved in

a limited number of reactions only, its presence or absence has fundamental impact on biogeochemical processes.

Aerobic degradation of organic matter

Aerobic respiration consumes a major part of the photosynthetically produced O₂ and about 90% of the organic matter (see Chapter *Carbon Cycle*). Aerobic (oxygen-metabolizing) organisms normally oxidize their substrates completely to CO₂. In most cases, O₂ is not directly involved in this process. Substrate oxidation generates reduced electron carriers by means of the respiratory chain. Oxygen is reduced as the last step of the respiration process.

Respiratory chain

Respiration is a membrane-bound process that generates a chemiosmotic proton gradient across the membrane (Mitchell, 1966). Respiratory chains are composed of series of enzymes, which are organized in multienzyme complexes and use cofactors that allow the stepwise transport of reducing equivalents to oxygen (Figure 1). In eukaryotes (plants, animals, fungi) it takes place within the mitochondria, which are assumed to have evolved from endosymbiotic bacteria. In prokaryotes (Bacteria, Archaea), the respiratory chain is located in the cytoplasmic membrane. The respiratory chain of the bacterium *Paracoccus denitrificans* appears to have many similarities to the mitochondrial type (Harold, 1986). However, many bacteria have variations compared to the mitochondrial type presented in Figure 1.

Energetics and ATP conservation

Most reducing equivalents are fed into the respiration process via NADH₂, which has a standard redox potential (E_0') of -0.32 V. The terminal electron-accepting redox pair O₂/H₂O has redox potential of $+0.82$ V. Thus, the usable redox potential is about 1.14 V. From this redox potential one can calculate a standard $\Delta G_0'$ of -440 kJ per mol of O₂. Assuming that ATP conservation requires about -75 kJ per mol, the conservation of 5 to 6 ATP per O₂ reduced is possible. As a consequence of the high ATP yield, aerobic organisms can form more biomass from the same amount of substrate than anaerobic organisms.

Use of oxygen as cosubstrate

Molecular oxygen is used as a cosubstrate in some catabolic and anabolic reactions (Lengeler et al., 1999). The enzymes involved are called mono- or di-oxygenases, depending on the number of oxygen atoms transferred to their substrate. Oxygenases are used by aerobes to activate certain substrates that do not have functional groups that allow a simple degradation. They catalyze the initial hydroxylation of hydrocarbons to yield alcohols that can easily be metabolized further. They are also involved in the ring cleavage of aromatic compounds and in the first oxidation step of ammonia oxydation. Anaerobic organisms are either unable to oxidize the substrates activated

Aerobic Metabolism, Figure 1 Principle of respiratory electron transport and vectorial proton translocation. The first proton translocating complex (with FMN and FeS as prosthetic groups) channels electrons to the quinones (UQ), which perform a cycle, again coupled to proton translocation. Electrons move on to the cytochrome bc_1 -complex, via cytochrome c to the copper-containing terminal cytochrome oxidase (Cyt aa_3). O_2 is reduced in the last step only. The ATP synthesis coupled to reentry of the translocated protons is independent of the electron transport process. (From Cypionka, 2006.)

by means of oxygenases or possess different degradation pathways.

Anabolic reactions making use of molecular oxygen are the biosynthesis pathways of tetrapyrroles, ubiquinones, pyrimidines, sterols, and unsaturated fatty acids. Again,

either the products are absent in strict anaerobes (e.g., sterols), or anaerobes have found alternative pathways for their biosynthesis.

Toxic forms of oxygen and detoxification

Aerobic metabolism inevitably generates small amounts of partially reduced toxic oxygen species (Lengeler et al., 1999). These are the superoxide anion ($O_2^{\cdot-}$), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($\cdot OH$). These species can be formed via nonenzymatic one-electron reduction steps (e.g., with Fe^{2+} , quinols, or H_2S) or by nonspecific reactions with reduced flavoproteins. Aerobic bacteria can remove toxic oxygen species by nonenzymatic reactions (e.g., with glutathione) or by means of enzymes: Superoxide dismutase (SOD) converts superoxide to H_2O_2 , and catalyze dismutates H_2O_2 to water and O_2 . These enzymes often lack in strict anaerobes, which might explain their sensitivity toward oxygen.

Distribution of the aerobic lifestyle

Many microorganisms can thrive in oxic (oxygen-containing) as well as in anoxic (free of oxygen) environments. Those are classified as facultative aerobes (or facultative anaerobes). This means that they can rely on aerobic respiration as well as on respiration with other electron acceptors or on fermentative energy conservation. Groups of strict anaerobes comprise methanogens, sulfate reducers, and Clostridia. Even in strict anoxic (oxygen-free) environments facultative aerobes can be found (Süß et al., 2006).

Summary

Aerobic respiration is the most effective way of energy conservation. It is used to oxidize the major part of the organic matter on Earth. During aerobic respiration oxygen is reduced to water. In some cases, O_2 is used by oxygenases for the hydroxylation of inert substrates. Aerobic organisms have enzymatic and nonenzymatic mechanisms to detoxify partially reduced oxygen species such as superoxide or hydrogen peroxide.

Algae (eukaryotic)

Eukaryotic algae are a collection of extremely diverse, nonrelated organisms that perform photosynthesis in plastids, permanent organelles of green, brown, or bluish colors derived from endosymbiosis. In contrast to plants, algae do not form embryos.

Algae is a term of convenience and refers to a collection of highly diverse organisms that undertake photosynthesis and/or possess plastids (Keeling, 2004). Many authors even include the prokaryotic cyanobacteria into the algae, because they exhibit a life-style rather similar to their eukaryotic counterparts and often share the same habitat with eukaryotic algae. Cyanobacteria form the origin of plastids (for reviews see McFadden, 2001; Keeling, 2004; Palmer, 2003). Plastids are the organelles of plants and eukaryotic algae that harbor photosynthesis and synthesize many chemical compounds also important for other biochemical pathways (e.g., aromatic amino acids, heme, isoprenoids, and fatty acids); nonphotosynthetic plastids are known from plants and many algal groups (Williams and Keeling, 2003). Recently, from strategies of synthesizing various information, that is, mainly DNA sequence analyses of concatenated genes as well as the incorporation of discrete characters such as insertions, deletions, and gene fusion events, and consideration of morphology and biochemistry, a phylogeny of eukaryotes has emerged which consists of five “supergroups” (Keeling, 2004). Algae are scattered among four of the five major eukaryotic groups. The “Plantae” comprises exclusively eukaryotes with plastids derived from primary endosymbiosis, that is, they are bound by two membranes, derived from the inner and outer membranes of a cyanobacterium which was transformed into an organelle through uptake and retention by the host cell followed by the loss of much of its genome (Keeling, 2004). The Plantae are formed by three distinct but related lineages, the viridiplantae (which comprises all green algae and land plants or embryophytes), the rhodophytes (red algae), and the glaucophytes. The “Chromalveolates” comprises large and abundant algal groups such as the heterokont algae (e.g., diatoms and brown algae), the haptophytes,

the alveolates (which include the dinoflagellates and apicomplexans), and the cryptomonads. Only a single lineage of each of the “Excavates” and “Rhizaria” includes algae, the euglenoids and chlorarachniophytes. Except for the Plantae, all other eukaryotic algal lineages acquired their plastids through secondary endosymbiosis (for reviews see McFadden, 2001; Keeling, 2004; Palmer, 2003). Secondary plastids are surrounded by four or three membranes which resulted from phagocytosis of a primary alga, which was either a red alga or a green alga. In secondary plastids of both red and green origin, the primary algal nucleus is highly reduced (in the cryptomonads and chlorarachniophytes) or more commonly lost altogether (e.g., in the heterokonts and haptophytes; Keeling, 2004).

Green algae (Plantae supergroup)

The green algae are photosynthetic eukaryotes with double membrane-bound plastids (derived from primary endosymbiosis), stacked thylakoids, and the chlorophylls *a* and *b*. Their other accessory pigments are the carotenoids, beta-carotene, and xanthophylls. The main reserve polysaccharide is starch which is deposited inside the plastid (Lewis and McCourt, 2004; Pröschold and Leliaert, 2007). A few genera (e.g., *Prototheca*) contain non-photosynthetic plastids which lost their pigments secondarily. Apart from plastid-associated features, a unique stellate structure linking nine pairs of microtubules in the flagellar base of those green algae that are motile or produce motile stages is characteristic, as well as cell walls composed of cellulose which is present in most green algae (Graham et al., 2009). Most of these characters are shared with embryophytes (land plants) and, therefore, the green algae are difficult to define to the exclusion of the latter. The green algae have evolved in two major lineages (Friedl, 1997; Karol et al., 2001; Lewis and McCourt, 2004). One lineage, the chlorophyte lineage (Chlorophyta *sensu* Bremer, 1985; Sluiman, 1985) comprises the majority of green algal diversity (i.e., the green algae in a more narrow sense or the majority of what have been traditionally called green algae) with a bewildering array of morphologies attributable to at least five different morphological organizations (Pröschold and Leliaert, 2007). Examples of microscopic green algae reported from freshwaters with high calcification levels are rather small coccoid forms (e.g., *Chlorella*-like, Figure 1a; *Desmochloris*, Figure 1d; *Pseudendocloniopsis*, Figure 1f), coccoids that form coenobia (e.g., *Scenedesmus*, Figure 1b) or are of filamentous organization which may easily disintegrate into unicells (e.g., *Stichococcus*, Figure 1c) or form small thalli of branched filaments (e.g., *Pseudendoclonium*, Figure 1e). Also some monadoid (flagellated unicells) green algae and the siphonocladous *Cladophora* are well known from highly calcifying freshwater habitats. Several marine green algae of coenocytic organization precipitate carbonate and belong to the

calcareous algae, for example, the orders Dasycladales (Kingsley et al., 2003) and Caulerpales (Stanley et al., 2010). Whether the aforementioned freshwater green algal taxa are involved in carbonate precipitation is still

unknown, but microscopic freshwater green algal genera with calcite deposits on their surfaces are several members of Zygnematales (e.g., *Oocardium*) and *Gongrosira* (Rott et al., 2009; Freytet and Verrecchia, 1998). The other major

green algal lineage, the charophyte clade (*sensu* Lewis and McCourt, 2004), contains a smaller number of widespread, mostly freshwater green algae. Examples from the charophyte clade which are associated with calcification are the orders Zygnematales and Charales, for examples, the genus *Chara* is known for its extracellular carbonate production (McConnaughey, 1991). The charophyte green algae represent the closer relatives of land plants (embryophytes) with the Charales being most closely related to embryophytes (Karol et al., 2001; Lewis and McCourt, 2004). In the three lineages of green algae where calcite accumulation is known, that is, the orders Caulerpales, Dasycladales and Zygnematales (Bilan and Usov, 2001), aragonite deposits are outside of the cell wall but inside a specialized sheath. The crystal bundles are organized in layers, which are parallel to the filaments of this porous multilayer sheath and have also calcium oxalate inclusions. The chemical composition of the sheath and its role in the calcification process are unknown for the majority of species. It may simply be a barrier preventing the diffusion into the surrounding medium, although its direct participation in the initiation of the crystal formation cannot be excluded (Bilan and Usov, 2001). A third group of green algal taxa, called prasinophytes, consists of “primitive”-appearing unicells of uncertain affinity. Most known prasinophyte green algae form several early diverging clades within the phylogeny of the Chlorophyta (Marin and Melkonian, 2010). The green flagellate genus *Mesostigma* may represent a very basal lineage of the charophyte clade (Charophyta), but some prasinophytes are likely representatives of even other early diverging clades (Fawley et al., 2000). With respect to the systematics of green algae, there is now consensus that the majority of known green algal species of the Chlorophyta belongs to three major lineages, the chlorophytes, trebouxiophytes, and ulvophytes, which are assigned to class rank (classes Chlorophyceae, Trebouxiophyceae, and Ulvophyceae; Pröschold and Leliaert, 2007). Green algae have an affinity to form symbioses with hosts of various phylogenetic positions. Well-known examples are green algae forming the photoautotrophic partners (photobionts) of fungal symbioses, that is, lichens, or representing the algal hosts (“Zoochlorellae”) of ciliates (Alveolates), heliozoa, sponges, and sea anemones (e.g., Summerer et al., 2008; Letsch et al., 2009).

Rhodophytes – red algae (Plantae supergroup)

Red algae are a very large and diverse group of microscopic algae and macroalgae. They are best known for their economic and ecological importance. Though they are present in freshwater with several genera, the majority of red algal genera occur on tropical and temperate marine shores, where they play important ecological roles (Graham et al., 2009). Certain calcified red algae, known as corallines, form hard, flat sheets

that consolidate and stabilize coral reef crests, that is, coralline red algae protect reefs from wave damage and, thus, they are regarded as important keystone organisms. Of well-known economic importance are the species of *Porphyra* and other red algal species which are grown in mariculture operations for use as human food. Several other marine genera are cultivated or harvested for the extraction of gelling polysaccharides such as agarose and carrageen (Graham et al., 2009).

Corallines are known from fossil records 500 million years old (Lower Ordovician; Riding et al., 1998). The oldest fossil record of a (non-coralline) red alga may represent the fossil taxon *Bangiomorpha pubescens* which was described from the 1,200-million-year-old Hunting Formation in the Canadian Arctic (Butterfield, 2000). It is most notable that *B. pubescens* even represents the earliest putative record for sex and taxonomically resolvable complex multicellularity among eukaryotes (Saunders and Hammersand, 2004). For a review of fossil records of the various taxonomic groups of red algae, see Saunders and Hammersand (2004).

The plastids of red algae lack chlorophyll *b* and *c*, but contain phycobilins (allophycocyanin, phycocyanin, and the red pigment phycoerythrin) as accessory pigments which are located in phycobilisomes on the outer surface of the thylakoids. The red algal plastids are bounded by two membranes and derived from a cyanobacterial primary endosymbiosis (Keeling, 2004). They produce floridean starch which is deposited in the cytoplasm. The rhodophytes lack flagella and centrioles in all stages of their life history (Graham et al., 2009).

The red algae (Rhodophyta) are a distinct eukaryotic lineage, whose members are united in the phylogenetic analyses of a nuclear, plastid, and mitochondrial genes (for review see Yoon et al., 2006). They belong to the Plantae supergroup of eukaryotes (Keeling, 2004) and are believed to form a sister group with the green line (Martin et al., 2002). Their divergence has been estimated ca. 1,500 million years ago (Yoon et al., 2004). Based on molecular evidence, the red algae are partitioned into seven classes, six of which have a rather simple body structure and reproduction (Yoon et al., 2006). The florideophytes (class Florideophyceae) are the monophyletic group of red algae that exhibit more complex bodies and reproduction (Saunders and Hammersand, 2004). The ecologically significant corallines, the economically important genus *Chondrus* (used as food and for the extraction of carrageen; Graham et al., 2009), and the vast majority of other modern red algal species are florideophytes; they are divided into several monophyletic groups (subclasses; Saunders and Hammersand, 2004; Le Gall and Saunders, 2007).

Coralline red algae represent not only a large carbon reservoir, but they also consolidate sediment and build landforms, and they occupy harder substrate in the

world's oceans than any other group of photosynthetic organisms. Unlike most other calcified algae that deposit carbonate as aragonite, the coralline red algae form calcite and it is believed that each family of coralline red algae is defined by only one crystalline modification of calcium carbonate (Borowitzka, 1977). The red algae show evidence of a surprising variety of calcification mechanisms, but the location of deposition is even more diverse. Mineralization may occur throughout the walls of nearly all vegetative cells, it may occur within the walls of only specialized cells, or it may be located in an intercellular organic matrix between cells, but not within the cell walls (Pueschel et al., 1992). Calcification in corallines is poorly understood, however, it seems clear that corallines deposit high magnesium calcite in a definitive pattern within their cell walls via the membrane pumps that control the flux of calcium and carbonate with the control of crystal orientation by organic wall components (Zankl, 2007). Coralline red algae can be the deepest algae (−50 to −110 m, Dullo et al., 1990) and many species occur in great abundance into the Arctic and subarctic. Coralline red algae in coral reefs are ubiquitous and dominant (Glynn et al., 1996; Keats et al., 1997), and their abundance in cryptic and shaded environments can be greatly underestimated (Littler, 1972). In temperate systems, the accumulation of unattached living or dead coralline algae forms large maerl beds (Martin et al., 2006). They also provide food for herbivores with hardened mouthparts (Steneck and Dethier, 1994) and surfaces for the settlement of invertebrate larvae (Adey, 1998). Coralline algal abundance, size, shape, and species composition in maerl beds vary considerably depending on their location, and several environmental factors influence coralline algal distribution. Maerl beds are highly sensitive to desiccation and are found from the low intertidal zone to depths of 150 m (Foster, 2001). Furthermore, coralline species are sensitive to seasonal variations in temperature inducing changes in their physiology, for example, *Lithothamnion* spp. growth rate increases with water temperature (Potin et al., 1990). Despite their ecological importance in temperate systems, primary production and calcification of coralline algae has been mainly investigated in tropical areas (Chisholm, 2003; Payri et al., 2001). A number of different associations between sponges and several species of red macroalgae have been described in literature (Trautman et al., 2000, 2002). The symbiotic association between the haplosclerid sponge *Haliclona cymiformis* and the red macroalga *Ceratodictyon spongiosum* is common on shallow coral reefs of the Indo-West Pacific, where it has been described as being one of the most conspicuous organisms found in these areas (van Soest, 1990). This symbiosis seems to be an obligatory association as neither sponge nor alga has ever been identified growing independently or in association with other species (Morrissey, 1980).

Glaucophytes (Plantae supergroup)

Glaucophytes (or glaucocystophytes) form a small group of microscopic algae exclusively found in freshwater environments; only about 13 species of glaucophytes have been described so far. They represent the third lineage of the plant supergroup, which is defined by plastids bound by a double membrane, that is, which is derived from primary cyanobacterial endosymbiosis (Keeling, 2004). Glaucophyte plastids are unique among plastids in that they are retaining the prokaryotic peptidoglycan layer between their two membranes. Therefore, they may represent an intermediate in the transition from a cyanobacterial endosymbiont to plastid; molecular phylogenetic analyses show the glaucophytes as the earliest divergence within the plant supergroup (Keeling, 2004; Martin et al., 2002). Glaucophyte plastids share the accessory photosynthetic pigments, phycobilins, which are organized in phycobilisomes (small particles on the outer surface of thylakoid membranes) with cyanobacteria and rhodophytes. For a review on glaucophytes, see Bhattacharya and Schmidt (1997) and Steiner and Löffelhardt (2002).

Photosynthetic stramenopiles (chromalveolates)

Stramenopiles form a monophyletic group of photoautotrophic as well as heterotrophic organisms which are characterized by swimming cells possessing at least one flagellum with distinct tripartite tubular hairs (Graham et al., 2009; Andersen, 2004). Most stramenopiles have two distinctly different flagella and, therefore, are also known as heterokonts. They have a long flagellum with tripartite hairs (tinsel or immature flagellum) to pull the cells through the water and a shorter smooth one (whiplash or mature flagellum) that lacks tripartite hairs, often with a light-sensing flagellar swelling at its base (Graham et al., 2009; Andersen, 2004). Photosynthetic stramenopiles or heterokont algae usually appear brown or golden brown (and are thus sometimes referred to as chromophytic algae) due to the presence of characteristic accessory pigments, fucoxanthin or vaucheriaxanthin, and at least one form of chlorophyll *c* (except in eustigmatophytes). The plastids are derived from a secondary endosymbiosis event with a red alga involved and surrounded by four membranes (McFadden, 2001; Keeling, 2004; Palmer, 2003). In most photosynthetic stramenopiles, a chloroplast endoplasmic reticulum is present, that is, plastid and nucleus are structurally connected. The photosynthetic stramenopiles comprise a tremendous morphological diversity: a large variety of unicellular or colonial algae, including the diatoms with silica frustules as walls, multicellular simple filaments (e.g., in the xanthophytes) as well as the macroscopic complex brown algae forming a brown canopy at sea shores. Based on detailed analyses of pigment composition, ultrastructure and molecular phylogenies more than a dozen of different classes of photosynthetic stramenopiles have been described (Graham

et al., 2009; Andersen, 2004). Some photosynthetic stramenopiles do not form mineralized cysts or scales and, therefore, they have no fossil record. Examples are the brown seaweeds (Phaeophyceae), the yellow green algae (Xanthophyceae), and the inconspicuous eustigmatophytes. In the context of geobiology also xanthophytes and eustigmatophytes may be important, as they have been reported from freshwaters with high calcite precipitation (see Figure 1g, e; Arp et al., 2010). However, their role in the calcification processes is still unclear. Therefore, in this entry, only those classes of photosynthetic stramenopiles will be discussed that produce mineralized cell coverings which are important in fossil deposits and, therefore, may be of particular interest in geobiology. Siliceous frustules define the diatoms (Bacillariophyta; see entry “*Diatoms*”), silica skeletons are characteristic for silicoflagellates (class Dictyochophyceae) and silica scales and cysts are commonly formed in synurophytes and chrysophytes.

Silicoflagellates are unicellular, flagellated, and photoautotrophic stramenopiles which are characterized in at least one life cycle stage by the formation of distinctive, one-piece external silica skeleton that is highly perforate. They form the order Dictyochaetales, one of three orders that have been described for the class Dictyochophyceae (Daugbjerg and Henriksen, 2001; Graham et al., 2009). Siliceous skeletons from silicoflagellates are common in fossil deposits dating back to the middle Cretaceous (ca. 120 million years ago). The skeletal remains in fossil material also indicate that species diversity reached a peak in the Miocene (ca. 23–25 million years ago), with more than 100 described species, but the diversity of silicoflagellates has decreased thereafter, leaving behind only two genera (Daugbjerg and Henriksen, 2001; Tappan, 1980). Biostratigraphic zonations have been developed for silicoflagellates in all oceans throughout the Cenozoic, though the zones typically range over longer intervals of time than foraminiferal or diatom zones (McCartney and Wise, 1990; McCartney and Harwood, 1992). Silicoflagellate skeletons may have considerable potential as ecophenotypic indicators (McCartney and Wise, 1990). Modern silicoflagellates are widespread in the oceans with a tendency to be more abundant in colder waters where they can even grow up to form blooms (Graham et al., 2009). Dictyochophytes occur in both marine and freshwater habitats (Moestrup, 1995; Moestrup and O’Kelly, 2000). *Synurophytes* and *chrysophytes* (often summarized as “Chrysophyte Algae”) produced an exceptional fossil record owing to the high preservation potential of their siliceous stomatocysts and scales (Smol, 1995; Andersen, 2004; Graham et al., 2009). In addition, they are highly sensitive to an array of limnological parameters. Synurophytes and Chrysophytes are close relatives in molecular phylogenies (Andersen, 2004); both share the capability to form stomatocysts, silica-walled resting stages, which arise sexually or asexually under unfavorable environmental conditions. The walls of stomatocysts

are so heavily silicified that they resist silica dissolution processes and thus accumulate in the sediments of lakes (Graham et al., 2009). Fossil records of stomatocysts extend back to the Lower Cretaceous (at least 150 million years ago). Synurophytes and chrysophytes are able to switch between autotrophy, heterotrophy, and even phagotrophy, which puts them at a distinct advantage in aquatic ecosystems that are low in nutrient concentrations and have reduced light penetration (Betts-Piper et al., 2004). From patterns of stomatocyst assemblages, past environmental conditions can be inferred making stomatocysts very important for paleolimnology (Duff et al., 1995; Siver, 1995; Wilkinson et al., 2001; Zeeb and Smol, 2001).

Synurophytes are unicellular or colonial silicated flagellates and despite they are photoautotrophic, many species are also capable of phagotrophy. Synurophycean cell surfaces are covered by overlapping silica scales, sometimes with spiny bristles, and are perforated (Graham et al., 2009). The scales’ perforation patterns are used as taxonomic features to delimitate species of synurophytes. A number of adhesive polysaccharides are involved in the scale attachment. The scales are produced in certain vesicles located on the surface of one of the plastids. In contrast to diatoms, synurophytes can continue to divide and function also in the absence of an external silica covering. In cultures of naked cells most cells will recover a complete cell covering when silicate is resupplied to silica-depleted cells (Leadbeater and Barker, 1995). Fossil scales similar to those of modern synurophytes have been reported from deposits of the middle Eocene (about 47 million years ago; Siver and Wolfe, 2005). Synurophyte scales can be used like stomatocysts for tracking environmental change using lake sediments (Zeeb and Smol, 2001; Wolfe and Perren, 2001). Synurophytes are abundant in neutral to slightly acidic freshwaters. Some species are regarded as indicators of low levels of pollution, but others are characteristic of eutrophic lakes (Graham et al., 2009).

Chrysophytes are golden-brown microalgae that are mostly unicellular or colonial which occur as flagellates or nonmotile cells; they include many unique and interesting morphologies (Graham et al., 2009). In contrast to synurophytes, scales covering the cell surface are absent in chrysophytes. Chrysophytes typically favor slightly acidic freshwaters of moderate to low productivity; their abundance and species richness increase with lake eutrophic status (Elloranta, 1995). Chrysophytes may have strong ecological impacts because many are mixotrophs, able to take up and metabolize dissolved organic compounds and particulate food as well as photosynthesize (Graham et al., 2009). Several chrysophytes are associated with the formation of undesirable blooms because living cells of certain species can produce toxic fatty acids that affect fish or excrete aldehydes and ketones into the water which can give it an unpleasant taste and odor.

Coccolithophorids and haptophyte algae (chromalveolates)

Haptophyte algae are a monophyletic group that includes all photosynthetic organisms with a haptonema. However, haptophytes also include some nonphotosynthetic relatives, and some that have secondarily lost the haptonema (Andersen, 2004). The haptonema, from which the group derives its name, is a microtubule-supported appendage that lies between two approximately equal flagella (for a review, see Inouye and Kawachi, 1994). Most haptophytes are marine, occurring in significant abundances even at greater water depth (up to 200 m). Haptophyte algae share many features, for example, pigment composition, presence of a chloroplast endoplasmatic reticulum, and plastids derived from red algal secondary endosymbiosis with the photosynthetic stramenopiles (Andersen, 2004). Based on structural and molecular evidences the haptophytes form a monophyletic lineage, treated as phylum Haptophyta which is divided into two classes (Edvardsen et al., 2000; Andersen, 2004). The larger group, class Coccolithophyceae, comprises the coccolithophorids which are haptophytes with a cell coat of mineralized scales (coccoliths) and two equal flagella or lack flagella altogether. Coccoliths are largely composed of calcium carbonate crystals in the form of calcite. There are two types of coccoliths, holococcoliths and heterococcoliths. In case of holococcoliths, an organic scale consisting largely of cellulose and produced by the Golgi body is secreted to the cell surface and then calcite crystals which are held together by organic material are deposited on the scale. In contrast, heterococcoliths develop on organic scales before being secreted from the cell, that is, calcite crystal deposition is already within the cell. The calcite crystals grow and interlock gradually forming the complex shape of the mature coccolith (deVrind-deJong et al., 1994; Probert et al., 2007; Graham et al., 2009). Coccoliths do not degrade at normal ocean pH and thus accumulate on the ocean floor. Therefore, coccolithophorids have produced huge amounts of sedimentary carbonates.

Coccolithophorids remove large quantities of atmospheric CO₂ through their photosynthesis and calcification and, therefore, are an important component of the global carbon cycle (McConnaughey, 1994), accounting for a substantial part of the ocean floor limestone sediments. Coccolithophorids contribute at least 25% of the total annual vertical transport of inorganic carbon to the deep ocean (Rost and Riebesell, 2004). Coccolithophorids have an excellent fossil record with fossil coccoliths well over 200 million years old. The abundance of coccolith fossils peaked during the late Cretaceous (63–95 million years ago) when extensive chalk deposits were laid down. Coccoliths are widely used as stratigraphic indicators and fossil coccoliths are widely used as bioindicators in the oil industry and as indexes of past climate and ocean chemistry conditions (Young et al., 1994).

Haptophytes are ecologically significant in terms of both biotic interactions and biogeochemistry. Haptophyte algae are considered as high-quality foods for zooplankton; several species contain nutritionally important polyunsaturated fatty acids which make them also commercially valuable for the production of fish in aquaculture systems. Other coccolithophytes may produce toxins that destroy cell membranes or produce copious amounts of organic slime and foam (Graham et al., 2009). Many coccolithophorids form blooms in ocean waters and produce large amounts of a volatile sulfur-containing molecule, dimethyl sulfide (DMS) that enhances cloud formation and increases acid rain (Malin and Steinke, 2004). Another cooling effect on the climate comes from the coccoliths which readily reflect light, thereby increasing reflectance of the ocean's surface.

Dinoflagellates (chromalveolates)

The dinoflagellates are an important group of phytoplankton in marine and freshwaters. Their adaptation to a wide variety of environments is reflected by a tremendous diversity in form and nutrition and an extensive fossil record dating back several hundred million years (Graham et al., 2009). Dinoflagellate cells have two structurally distinct flagella whose motion causes the cells to rotate as they swim, but also nonflagellate unicells and filamentous forms of dinophytes are known. Two different cell types can be distinguished on the basis of the cell-wall covering or theca. The “naked” or unarmored forms have an outer plasmalemma surrounding a single layer of flattened vesicles (membrane sacs or alveoli). Armored dinoflagellates have cellulose or other polysaccharides within each vesicle, giving the cells a more rigid, inflexible wall. These cellulose plates are arranged in distinct patterns which are extensively used as taxonomic “fingerprints” (Hackett et al., 2004). Cells of armored dinoflagellates display conspicuous anterior–posterior and dorsal–ventral differentiation. Their cells consist of two parts, separated by a groove that encircles the cell and contains the transverse flagellum which is flattened, ribbon-shaped, and with a single row of hairs. A smaller groove is mostly extending into the posterior cell part and contains the longitudinal flagellum which has two rows of hairs; it is directed posterior and emerges from the cell (Graham et al., 2009; Hackett et al., 2004).

Success of dinoflagellates as phytoplankton may be due in part to unique behavior patterns, including diel vertical migration and their capability to live phagotrophic (feeding on particles such as the cells of other organism) in addition to photoautotrophy (mixotrophic life-style). Some of the armored or thecate heterotrophic dinoflagellates have developed a remarkable pseudopod-like structure that is extruded from the cell and flows around the prey, enveloping it so the contents can then be digested (Hackett et al., 2004). Some dinoflagellates produce toxins that are dangerous to man, marine mammals, fish,

seabirds, and other components of the marine food chain (Van Dolah, 2000). Others are bioluminescent and emit light; some function as parasites or symbionts that rely on host organisms for part of their nutrition. Many photosynthetic dinoflagellates live as endosymbionts with reef-building corals. Stimulated by chemical signals from their animal hosts, dinoflagellate endosymbionts provide the corals with essential organic food.

Therefore, the dinoflagellate symbionts are critical components of the coral reef ecosystems whose loss during stress-related “bleaching” events can lead to mass mortality of coral hosts and associated collapse of reef ecosystems (Baker, 2003). Also, the high rates of calcification and production that characterize typically oligotrophic coral reef ecosystems are largely credited to the mutualistic symbiosis between the scleractinian corals and photosynthetic dinoflagellates belonging to the genus *Symbiodinium* (Apprill and Gates, 2007). Corals with a dinoflagellate symbiont calcify much faster than those without – an effect linked to photosynthetic fixation of CO₂ by the dinoflagellates (Marshall, 1996). A significant amount of photosynthetic product is excreted by the symbiotic dinoflagellates, primarily as glycerol. Up to 50% of the fixed carbon may be transferred to the host (Paracer and Ahmadjian, 2000), in which it is converted mainly to lipids and proteins. On the dinoflagellate side, many of these symbioses occur in oligotrophic waters in which nutrients are scarce in the water column (Hackett et al., 2004). In other symbiotic dinoflagellate associations, the hosts include foraminifera, radiolarians, flatworms, anemones, jellyfish, and even bivalve mollusks (Hackett et al., 2004).

Undisputed structural fossils of dinoflagellates occur some 200 million years or so ago (Graham et al., 2009). These fossils, known as hystrichospheres, resemble resting stages of some modern dinoflagellates. Some modern dinoflagellates produce resting cysts or zygotes with an organic compound resistant to decay and thus aid the survival of dinoflagellate fossils, of which a considerable diversity has been described (Fensome et al., 2003). Other chemical compounds thought to be specific to dinoflagellates have already been found in Proterozoic (Precambrian) rocks and such chemical fossils suggest that dinoflagellate-like organisms might have existed already more than 600 million years ago (Graham et al., 2009).

Many dinoflagellates are photosynthetic and, through endosymbiosis, have acquired a wide diversity of plastids from distant evolutionary lineages. The most common plastid in dinoflagellates is golden brown with a unique accessory pigment, peridinin; they also contain chlorophyll *c*. Such peridinin plastids are bounded by three membranes and are derived from red algal secondary endosymbiosis (Delwiche, 2007; Hackett et al., 2004). A number of dinoflagellates have plastids from haptophytes, diatoms, green algae, or cryptomonads which may have replaced preexisting peridinin plastids (tertiary endosymbiosis; McFadden, 2001; Keeling, 2004; Palmer, 2003).

A small group of dinoflagellates with peridinin plastids produce calcareous structures, formed during the life cycle or found in vegetative stages (Gottschling et al., 2005). The potential to produce calcareous structures has been considered as apomorphic within alveolates (Kohring et al., 2005), arguing for the monophyly of the family Calciodinellaceae which comprises approximately 30 (recognized) extant species that are distributed in cold through tropical seas of the world. Calcareous cysts are deposited in both sediments coastal (Montresor et al., 1998; Persson et al., 2000) and oceanic (Vink, 2004; Zonneveld et al., 1999). According to the fossil record, calcareous dinoflagellates originate in the Upper Triassic (Janofske, 1992) and are highly diverse during the Cretaceous and throughout the Tertiary (Keupp, 1991; Kohring, 1993; Willems, 1994), thus many fossil species (namely their cysts) have been described (Gottschling et al., 2005). Based on morphological and molecular data, calcareous dinoflagellates (Thoracosphaeraceae, Peridinales) are a monophyletic group comprising three major clades (Gottschling et al., 2008).

Other chromalveolates

Cryptomonads. Recent molecular phylogenetic analyses indicate that the cryptomonads and the haptophyte algae together form a monophyletic group (Hackett et al., 2007) and, therefore, also belong to the Chromalveolates supergroup. Cryptomonads form an abundant group of marine and freshwater unicellular flagellates that contain a plastid derived from red algal secondary endosymbiosis with chlorophyll *a* and *c* surrounded by four membranes. Cryptomonad plastids have received some attention because they are one of only two groups in which the primary algal nucleus has not been completely lost; they retain a small relict nucleus called a nucleomorph (McFadden, 2001; Keeling, 2004; Palmer, 2003).

Apicomplexa are a large group composed entirely of obligate intracellular parasites, including several that cause significant diseases such as malaria. As intracellular parasites, the discovery of a relict plastid (or apicoplast) in apicomplexa bounded by four membranes has drawn a great deal of attention as an evolutionary novelty and possible drug target (Keeling, 2004). There is current evidence indicating that this plastid is derived from a red alga and that the apicomplexa share a monophyletic origin with all other groups with plastids from red algal secondary endosymbiosis. The apicomplexa may be most closely related with the dinoflagellates (Moore, 2008). For a review of apicomplexa relating to their plastids, see Foth and McFadden (2003).

Algal groups with plastids derived from green algal secondary endosymbiosis

Chlorarachniophytes (Rhizaria supergroup). Chlorarachniophytes are a relatively rare group of marine amoeboid flagellates and flagellates that contain a green algal plastid (chlorophyll *a* and *b*) bounded by four membranes. They

contain a relict nucleus, nucleomorph, which has been retained from the green algal symbiont (McFadden, 2001; Keeling, 2004; Palmer, 2003). Chlorarachniophytes form a monophyletic group within the Rhizaria supergroup of eukaryotes (Ishida et al., 1999).

Euglenids (Excavates supergroup). Euglenids are a diverse group of common marine and freshwater flagellates, about half of which contain a plastid derived from green algal secondary endosymbiosis which is bounded by three membranes and contains chlorophyll *b* as accessory pigment. The remainder of the group are osmotrophs or heterotrophs that feed on bacteria or other eukaryotes. Molecular phylogenies show that photosynthetic euglenids may have acquired their plastids from a green alga relatively late in evolution, despite the Euglenozoa may be a rather old group. Euglenids are closely related to the parasitic trypanosomes (Kinetoplastids), together with diplomonids, making up the monophyletic Euglenozoa. Distinguishing features of euglenids are that they produce a storage carbohydrate which is a β -1,3-linked glucan (paramylon) in their cytoplasm and that they display a unique surface structure composed of parallel ribbon-like proteinaceous strips. For reviews of euglenids, see Leedale and Vickerman (2000), Milanowski et al. (2006) or Ciugulea and Triemer (2010).

Summary

Algae is a term of convenience and refers to a collection of highly diverse organisms that undertake photosynthesis and/or possess plastids. In addition, the photoautotrophic cyanobacteria are regarded as algae by some authors. In a recent phylogeny of the eukaryotes, the algae are scattered among four of the five recognized supergroups. A single primary endosymbiosis with a cyanobacterium may have been the start of all eukaryotic algae which first diverged into the green algae, red algae, and glaucophytes (Plantae supergroup). The plastids of all other algal lineages derived from secondary endosymbiosis involving either a red algal cell (algae of the Chromalveolates supergroup) or green algal cells (euglenids and chlorarchniophytes, Excavates and Rhizaria supergroups). Many algae form symbioses with ciliates and some metazoa. Algae are very important primary producers in almost every aquatic or terrestrial habitats and are important key players within the carbon and silica cycles for the major part of Earth history. Many lineages have produced significant fossil records due to their ability to precipitate calcium carbonate on their cell surfaces (red algae, some dinoflagellates) or form calcified (haptophytes) or silicified body scales, silica endoskeletons, resting stages, or cell walls (photoautotrophic stramenopiles, including dictyochophytes, synurophytes, chrysophytes, and diatoms). Due to their high sensitivity to certain environmental parameters and their high preservation potential, these algae also play important roles as sedimentary bioindicators in tracking environmental changes.

ALKALINITY

Andreas Reimer, Gernot Arp
University of Göttingen, Göttingen, Germany

The term “Alkalinity,” commonly denoted by TA (also A_T , ALK, and others) and then called titration alkalinity or total alkalinity, refers to a very important chemical concept in aquatic chemistry. Total alkalinity is one of the few measurable quantities in natural waters that allows, together with other properties, to calculate concentrations of single species of the carbonate system such as CO_2 , HCO_3^- , CO_3^{2-} , H^+ , and OH^- (Wolf-Gladrow et al., 2007), and further on, the saturation state of the waters with respect to certain carbonate minerals. Therefore, alkalinity represents a hydrogeochemical key parameter for the understanding of carbonate precipitation, either biologically mediated or not, and its variation through the geological history.

Definition

From its determination by titrimetric techniques, alkalinity has historically been defined as the number of equivalents of a strong acid required to neutralize 1 L of water at 20°C. The obtained end-point, corresponding to the second equivalence point of the carbonate system, was operationally defined and results were then commonly given as eq L^{-1} . The recent definition of alkalinity is based on the implementation of the Brønsted–Lowry concept of acids and bases by Rakestrow (1949) who defined alkalinity as the excess of bases (proton acceptors) over acids (proton donors). Considering seawater, alkalinity is mostly determined by the ions bicarbonate and carbonate, also by the borate ion, and to a smaller extent by OH^- and H^+ from

dissociation of water. Alkalinity then refers to the proton condition with reference to a zero level of protons defined by the species H_2CO_3 , $\text{B}(\text{OH})_3$, and H_2O , where the proton acceptors are HCO_3^- , CO_3^{2-} , $\text{B}(\text{OH})_4^-$, and OH^- and the proton donor is H^+ . That is, alkalinity is the equivalent sum of bases that have one or two protons less than the reference species minus H^+ (or H_3O^+) that has one proton more than H_2O (Dickson, 1981; Stumm and Morgan, 1996; Zeebe and Wolf-Gladrow, 2001). The expression for the total alkalinity is thus presented as

$$\text{TA} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{B}(\text{OH})_4^-] + [\text{OH}^-] - [\text{H}^+],$$

where conceptually the right hand term can be divided up in carbonate alkalinity ($\text{CA} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}]$) as the most dominant contributor, borate alkalinity, and water alkalinity.

Natural waters may contain various acid–base systems that can accept and donate protons other than or in addition to carbonic acid or boric acid. These complications have been taken into account currently in the most precise definition of total alkalinity of Dickson (1981) (compare also Dickson, 1992; DOE, 1994; and recent extension by Wolf-Gladrow et al., 2007). The definition is unequivocally based on a chemical model of occurring acid–base processes and to be independent of temperature and pressure expressed in gravimetric units (mol kg^{-1}). In Dickson’s concept, the total alkalinity (TA) is defined as the number of moles of hydrogen ion equivalent to the excess of proton acceptors over proton donors with respect to the proton condition defined by the value $\text{p}K = 4.5$ in 1 kg of sample. Bases formed from weak acids with a dissociation constant $K \leq 10^{-4.5}$ are considered proton acceptors, acids with $K > 10^{-4.5}$ are proton donors, and the chemical species defining the zero level of protons of the various acid–base systems are H_2CO_3 , $\text{B}(\text{OH})_3$, H_2O , H_2PO_4^- , H_4SiO_4 , NH_4^+ , H_2S , SO_4^{2-} , F^- , and NO_2^- . From this definition the expression for the total alkalinity is presented as

$$\begin{aligned} \text{TA} = & [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{B}(\text{OH})_4^-] + [\text{OH}^-] \\ & + [\text{HPO}_4^{2-}] + 2[\text{PO}_4^{3-}] + [\text{H}_3\text{SiO}_4^-] \\ & + [\text{NH}_3] + [\text{HS}^-] + \dots - [\text{H}^+] - [\text{HSO}_4^-] \\ & - [\text{HF}] - [\text{H}_3\text{PO}_4] - [\text{HNO}_2] \dots \end{aligned}$$

where the ellipses stand for additional acid–base species (Wolf-Gladrow et al., 2007).

An alternative definition for alkalinity derives when considering the charge balance of natural waters (Stumm and Morgan, 1996). From the principle of electroneutrality total alkalinity can be expressed in terms of the charge imbalance between the equivalent sum of conservative cations (base cations of strong bases) and the sum of conservative anions (conjugate bases of strong acids). For the total alkalinity of sea water dominated by

University of Göttingen, Göttingen, Germany

The term “Alkalinity,” commonly denoted by TA (also A_T , ALK, and others) and then called titration alkalinity or total alkalinity, refers to a very important chemical concept in aquatic chemistry. Total alkalinity is one of the few measurable quantities in natural waters that allows, together with other properties, to calculate concentrations of single species of the carbonate system such as CO_2 , HCO_3^- , CO_3^{2-} , H^+ , and OH^- (Wolf-Gladrow et al., 2007), and further on, the saturation state of the waters with respect to certain carbonate minerals. Therefore, alkalinity represents a hydrogeochemical key parameter for the understanding of carbonate precipitation, either biologically mediated or not, and its variation through the geological history.

Definition

From its determination by titrimetric techniques, alkalinity has historically been defined as the number of equivalents of a strong acid required to neutralize 1 L of water at 20°C. The obtained end-point, corresponding to the second equivalence point of the carbonate system, was operationally defined and results were then commonly given as eq L^{-1} . The recent definition of alkalinity is based on the implementation of the Brønsted–Lowry concept of acids and bases by Rakestrow (1949) who defined alkalinity as the excess of bases (proton acceptors) over acids (proton donors). Considering seawater, alkalinity is mostly determined by the ions bicarbonate and carbonate, also by the borate ion, and to a smaller extent by OH^- and H^+ from

dissociation of water. Alkalinity then refers to the proton condition with reference to a zero level of protons defined by the species H_2CO_3 , $\text{B}(\text{OH})_3$, and H_2O , where the proton acceptors are HCO_3^- , CO_3^{2-} , $\text{B}(\text{OH})_4^-$, and OH^- and the proton donor is H^+ . That is, alkalinity is the equivalent sum of bases that have one or two protons less than the reference species minus H^+ (or H_3O^+) that has one proton more than H_2O (Dickson, 1981; Stumm and Morgan, 1996; Zeebe and Wolf-Gladrow, 2001). The expression for the total alkalinity is thus presented as

$$\text{TA} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{B}(\text{OH})_4^-] + [\text{OH}^-] - [\text{H}^+],$$

where conceptually the right hand term can be divided up in carbonate alkalinity ($\text{CA} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}]$) as the most dominant contributor, borate alkalinity, and water alkalinity.

Natural waters may contain various acid–base systems that can accept and donate protons other than or in addition to carbonic acid or boric acid. These complications have been taken into account currently in the most precise definition of total alkalinity of Dickson (1981) (compare also Dickson, 1992; DOE, 1994; and recent extension by Wolf-Gladrow et al., 2007). The definition is unequivocally based on a chemical model of occurring acid–base processes and to be independent of temperature and pressure expressed in gravimetric units (mol kg^{-1}). In Dickson’s concept, the total alkalinity (TA) is defined as the number of moles of hydrogen ion equivalent to the excess of proton acceptors over proton donors with respect to the proton condition defined by the value $\text{pK} = 4.5$ in 1 kg of sample. Bases formed from weak acids with a dissociation constant $K \leq 10^{-4.5}$ are considered proton acceptors, acids with $K > 10^{-4.5}$ are proton donors, and the chemical species defining the zero level of protons of the various acid–base systems are H_2CO_3 , $\text{B}(\text{OH})_3$, H_2O , H_2PO_4^- , H_4SiO_4 , NH_4^+ , H_2S , SO_4^{2-} , F^- , and NO_2^- . From this definition the expression for the total alkalinity is presented as

$$\begin{aligned} \text{TA} = & [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{B}(\text{OH})_4^-] + [\text{OH}^-] \\ & + [\text{HPO}_4^{2-}] + 2[\text{PO}_4^{3-}] + [\text{H}_3\text{SiO}_4^-] \\ & + [\text{NH}_3] + [\text{HS}^-] + \dots - [\text{H}^+] - [\text{HSO}_4^-] \\ & - [\text{HF}] - [\text{H}_3\text{PO}_4] - [\text{HNO}_2] \dots \end{aligned}$$

where the ellipses stand for additional acid–base species (Wolf-Gladrow et al., 2007).

An alternative definition for alkalinity derives when considering the charge balance of natural waters (Stumm and Morgan, 1996). From the principle of electroneutrality total alkalinity can be expressed in terms of the charge imbalance between the equivalent sum of conservative cations (base cations of strong bases) and the sum of conservative anions (conjugate bases of strong acids). For the total alkalinity of sea water dominated by

HCO_3^- , CO_3^{2-} , and B(OH)_4^- , the expression may be presented by

$$\text{TA} = [\text{Na}^+] + [\text{K}^+] + 2[\text{Mg}^{2+}] + 2[\text{Ca}^{2+}] \\ - [\text{Cl}^-] - [\text{Br}^-] - [\text{NO}_3^-] - 2[\text{SO}_4^{2-}],$$

which is equivalent to the above definition in terms of proton acceptors and donors

$$\text{TA} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{B(OH)}_4^-] \\ + [\text{OH}^-] - [\text{H}^+].$$

In the charge balance expression quantities are defined to be conservative with respect to mixing and changes in temperature (T) and pressure (P) provided that concentrations are on the gravimetric unit scale (mol kg^{-1}). Thus, from the TA expression entirely in terms of conservative ions TA is a conservative quantity too. In contrast, the concentrations of individual species of, e.g., the carbonate system may change with temperature and pressure because of the T - P dependency of the equilibrium constants.

Following the charge balance approach, Zeebe and Wolf-Gladrow (2001) and Wolf-Gladrow et al. (2007) have derived an expression in terms of total concentrations of conservative ions and conservative total concentrations of the various acid-base species under concern in the definition of Dickson (1981) in terms of an acid-base balance. This derived expression for TA is denoted as the explicit conservative alkalinity expression (TA_{ec}).

$$\text{TA}_{\text{ec}} = [\text{Na}^+] + [\text{K}^+] + 2[\text{Mg}^{2+}] + 2[\text{Ca}^{2+}] + \dots \\ - [\text{Cl}^-] - [\text{Br}^-] - [\text{NO}_3^-] - \dots \\ - 2\text{TSO}_4 - \text{THF} - \text{TPO}_4 - \text{THNO}_2 + \text{TNH}_3,$$

where total concentrations terms represent concentrations sums of the species of the acid-base systems $\text{TSO}_4 = [\text{SO}_4^{2-}] + [\text{HSO}_4^-]$, $\text{THF} = [\text{F}^-] + [\text{HF}]$, $\text{TPO}_4 = [\text{H}_3\text{PO}_4] + [\text{H}_2\text{PO}_4^-] + [\text{HPO}_4^{2-}] + [\text{PO}_4^{3-}]$, $\text{THNO}_2 = [\text{NO}_2^-] + [\text{HNO}_2]$, $\text{TNH}_3 = [\text{NH}_3] + [\text{NH}_4^+]$, and ellipses stand for additional ions with minor concentrations.

The definition of TA_{ec} has the advantage that each term in the expression is conservative with respect to T - P changes, even though single species in the total concentration terms may be not. In particular, the approach is very convenient to derive changes of TA due to certain physicochemical and biogeochemical processes such as nutrient uptake in biological production and release during remineralization.

Sources, changes, and ranges

The primary source of alkalinity in surficial (and subsurface) waters is carbonic acid-controlled chemical weathering of carbonates, aluminum-silicate minerals like feldspars or Mg-Fe-silicates. The overall concentration and subsequent changes in alkalinity of water are therefore determined by the geology of the watershed, the

predominant weathering reactions and ion exchange in the soils, and concomitant biogeochemical processes.

TA as a conservative quantity will first alter with changes in salinity as a result of precipitation, evaporation, and mixing. Contrariwise to its increase from dissolution of limestone carbonates TA decreases when biogenic or non-biogenic CaCO_3 or other carbonate minerals precipitate. Further important changes are due to various biogeochemical processes. It has to be noted that total alkalinity does not change as a result of CO_2 exchange with the atmosphere. Invasion or degassing of CO_2 affects the adjustment of the carbonate species (ratio of $[\text{HCO}_3^-]$ to $[\text{CO}_3^{2-}]$) and the pH but not TA. Therefore, it is also not the consumption of CO_2 during photosynthesis or release during aerobic respiration that brings about a change in TA, but the utilization or remineralization of nitrate and phosphate involved in the processes. Nitrogen assimilation in form of ammonia decreases TA and no change of TA results from molecular nitrogen uptake (Stumm and Morgan, 1996; Wolf-Gladrow et al., 2007). Several microbially mediated processes lead to a change in alkalinity where deviation in the charge balance is compensated by yield or consumption of H^+ or OH^- . When oxygen is consumed in processes like nitrification, oxygenation of soluble ferrous iron to ferric oxide or sulfide oxidation from HS^- or pyrite total alkalinity decreases. Under anoxic conditions, remineralization of organic matter by denitrification, reduction of iron and manganese oxides and sulfate reduction frequently result in large increases of total alkalinity (Lerman and Stumm, 1989; Stumm and Morgan, 1996).

Depending on the rock mineralogy of the catchment area and prevalent vegetation total alkalinity in streams and inland lakes commonly ranges below 3 mmol kg^{-1} . Very low alkalinity is bound to tributaries and lakes in crystalline rock areas or to acidic bog and peatland waters. Here, H^+ released by biomass exceeding H^+ consumption by soil weathering results in an excess of protons that is referred to as “mineral acidity” or in turn “negative alkalinity” (Stumm and Morgan, 1996). On the other hand, in hard-water creeks that gain their alkalinity preferably from the dissolution of limestone rocks TA may reach values of 4 mmol kg^{-1} to 6 mmol kg^{-1} close to their spring sites.

In the oceans, TA typically ranges from 2.2 mmol kg^{-1} to 2.5 mmol kg^{-1} where changes with depth are mainly associated with the production and dissolution of calcareous organisms (Broecker and Peng, 1982). Higher TA is found in today's only anaerobic ocean basin, the Black Sea, where alkalinity increases to about 4.5 mmol kg^{-1} in the anoxic bottom waters in the course of oxidation of organic material by sulfate reduction (Kempe, 1990; Hiscock and Millero, 2006). Also due to enhanced sulfate reduction and frequently complementing methane oxidation, TA in the order of $10^{-2} \text{ mol kg}^{-1}$ can accumulate in pore waters of marine sedimentary successions (Schulz and Zabel, 2000).

Even higher total alkalinity is typical for highly alkaline salt lakes, so-called soda lakes, which receive an equivalent load of HCO_3^- and CO_3^{2-} in excess to Mg^{2+} and Ca^{2+} from their riverine inflows. Here, TA can rise to

more than $10^{-1} \text{ mol kg}^{-1}$ and pH increase above 10 in the course of evaporation and subsequent Ca-carbonate precipitation while alkali cations, in particular sodium and potassium, increasingly maintain the charge balance of bicarbonate and carbonate ions (e.g., Lerman and Stumm, 1989; Kempe and Kazmierczak, 1994; Reimer et al., 2009).

Alkalinity and carbonate precipitation

Alkalinity, together with any of the three other measurable properties of the carbonate system – pH, dissolved inorganic carbon (DIC or $C_T = [\text{CO}_2] + [\text{HCO}_3^-] + [\text{CO}_3^{2-}]$), or PCO_2 (partial pressure of CO_2) – can be used to compute the remaining quantities including concentrations of

Alkalinity, Figure 1 (Continued)

single species such as HCO_3^- and CO_3^{2-} . From CO_3^{2-} and Ca^{2+} concentrations (or more precise activities) saturation with respect to carbonate minerals is determined, where saturation Ω is given by the product of the actual ion activities ($\text{IAP} = \{\text{Ca}^{2+}\} \times \{\text{CO}_3^{2-}\}$) divided by the solubility product of the carbonate (K_{mineral}) at ambient temperature and pressure ($\Omega_{\text{mineral}} = \text{IAP}/K_{\text{mineral}}$). A commonly used alternative notation is the saturation index (SI) which is defined as $\log \Omega$ ($\text{SI}_{\text{mineral}} = \log (\text{IAP}/K_{\text{mineral}})$).

The oceanic CaCO_3 saturation state is primarily determined by variation of the CO_3^{2-} ion concentration, because the Ca^{2+} concentration closely depends on salinity and does not vary substantially. In the upper ocean, CO_2 removal by primary production increases CO_3^{2-} concentrations resulting in an about fivefold supersaturation ($\text{SI} = 0.7$) with respect to calcite. On the other hand, biologically controlled calcification of calcareous plankton or reefal organisms is responsible for the lower alkalinity of about $2.2\text{--}2.3 \text{ mmol kg}^{-1}$ in surface seawater. In turn, supersaturation decreases with depth when CO_2 is released by remineralization of sinking organic matter when temperature and pressure changes. In the deeper ocean, total alkalinity then increases to about $2.4\text{--}2.5 \text{ mmol kg}^{-1}$ reflecting the dissolution of sinking calcium carbonate particles in response to the lower saturation state (e.g., Broecker and Peng, 1982; Morse and Mackenzie, 1990).

As one of the major factors in the oceanic carbonate system, alkalinity distribution and behavior in the oceans has thoroughly been investigated during the last decades. Dissolution-preservation patterns of biogenic carbonates in surface to deep oceans and the changes brought about by a rising atmospheric CO_2 level (Feely et al., 2004) have been assessed within global ocean research programs, as well as general feedbacks between the oceanic carbonate and the global climate system. Contrary to this rising knowledge on the modern marine environment, estimates

of ocean alkalinity throughout geological history are rare and, in the lack of direct analytical proxies, mainly rely on model assumptions. Ocean alkalinity comparably high as modern values is suggested for the Cenozoic and late Mesozoic (Tyrrell and Zeebe, 2004; Ridgwell, 2005). During periods of the Mesozoic and Paleozoic, alkalinity about two to three times higher than recent can be assumed according to the evolution of the Phanerozoic atmospheric CO_2 (Ridgwell, 2005), fluctuations in the rate of continental weathering (Locklair and Lerman, 2005), or the more widespread occurrence of anoxic basins (Kempe and Kazmierczak, 1994). Elevated alkalinity concentrations of some tenths of mmol kg^{-1} are suggested for the Earth's primordial ocean in favor of a slightly acidic to neutral Na-Cl-dominated chemistry under an early CO_2 -rich atmosphere (Grotzinger and Kasting, 1993; Morse and Mackenzie, 1998). Alternatively, even higher alkalinity has been postulated for a Precambrian alkaline "Soda Ocean" in analogy to modern Na-carbonate-dominated soda lakes (Kempe and Degens, 1985).

In principle, precipitation of CaCO_3 is kinetically unfavorable even at the fivefold supersaturation of the modern ocean (e.g., Morse and He, 1993). Mechanisms to overcome this kinetic inhibition evolved at the Precambrian-Cambrian boundary with the advent of controlled biomineralization that became a major regulator of carbonate precipitation since the Mesozoic proliferation of the calcareous plankton. Prior to the Cambrian, carbonate deposition was characterized by sea-floor encrustations, cement beds, and the widespread occurrence of microbialites (Grotzinger, 1990; Riding, 2000), which are attributed to calcification of biofilms and microbial mats. In the lack of direct metabolic control on carbonate production, these Precambrian deposits are thought to have been formed under the pressure of a higher supersaturated environment, possibly still accounting for the dominance

Alkalinity, Figure 1 Recent environments that sustain microbialite growth illustrated in terms of alkalinity behavior and carbonate mineral saturation. (a–c) Shark Bay in Western Australia is one of the few recent marine examples that sustains calcifying biofilms involved in the formation of agglutinated stromatolites. Here, Indian Ocean water entering the embayment and running over the Faure sill into the Hamlin Pool to the SE is concentrated upon evaporation (a, courtesy to NASA). According to the twofold increase in salinity, alkalinity, and carbonate supersaturation rises continuously (b). The famous Hamlin Pool stromatolites (c) occur in the southernmost bay where alkalinity has increased to more than 2.8 mmol kg^{-1} and waters are nearly ten times supersaturated with respect to calcite. (d and e) Today, microbialite growth is also sustained in environments such as hardwater creeks such as the Westerhöfer Bach (Shiraishi et al., 2008), which are commonly characterized by calcium-bicarbonate type waters. From take-up of soil CO_2 and subsequent subsurface dissolution of limestone rocks, these creeks have gained already high total alkalinities ranging from 4 to 6 mmol kg^{-1} . Otherwise, at their spring sites initial pH (around 7) and carbonate saturation ($\text{SI}_{\text{cc}} = 0$) are low due to partial CO_2 pressures much higher than the atmospheric level ($\text{PCO}_2 = 10^{-2} \text{ atm}$). Continuous physicochemical CO_2 -degassing along the flowpath increases pH and CO_3^{2-} and therefore enforces supersaturation (d). Precipitation of CaCO_3 and formation of calcareous microbialites, so-called tufa stromatolites (e), commences when supersaturation reaches a certain maximum threshold level of 10- to 15-fold ($\text{SI} = 1.0\text{--}1.2$) (Arp et al., 2001), and results in the subsequent decline of alkalinity and Ca^{2+} concentrations in the creeks. (f and g) The crater lake of Satonda Island (f), Indonesia, filled with water of nearly marine composition, represents the case of a subrecent microbialite formation obviously induced by an enormous increase of alkalinity in its anoxic deep waters (Kempe and Kazmierczak, 1990). The multiple salinity stratification of the lake is a residue of former evaporitic phases. Especially in the bottom layer, sulfate has nearly been consumed due to bacterial reduction resulting in an exceptionally high total alkalinity of more than 50 mmol kg^{-1} , sulfide concentrations of up to 12 mmol kg^{-1} , and extremely high PCO_2 (more than 10^{-1} atm) (g). Alkalinity and carbonate supersaturation in the photic surface layer is determined by the seasonal mixing transfer of alkalinity from the monimolimnion top layer to the mixolimnion, degassing, rain water dilution, and evaporation (Arp et al., 2003). In the surface layer alkalinity reaches twice the value of open marine waters (4.1 mmol kg^{-1}) and the tenfold supersaturation may constitute the prerequisite for the present-day, though minor, calcification of biofilms.

of microbial carbonates in the early to middle Paleozoic (Riding and Liang, 2005). Today, the occurrence of carbonate deposits comparable to ancient microbialites is confined to particular environments such as restricted evaporational marine settings, freshwater habitats like tufa stromatolite forming hardwater creeks, or alkaline salt lakes (Figure 1). Although at first glance very different, these environments in common exhibit a significantly higher alkalinity than recent ocean values and a 10–15 fold supersaturation (i.e., $SI = 1\text{--}1.2$) with respect to calcite. Maintaining elevated carbonate supersaturation as found in these recent environments and as suggested for certain periods in Earth's history calls for variation in alkalinity in paleo-ocean model calculations (Locklair and Lerman, 2005). Therefore, changes in alkalinity may be considered as an underappreciated hydrogeochemical key mechanism with regard to carbonate supersaturation and carbonate deposition in its various forms through geologic times.

Fossil resin; Resinite

Definition

Fossilized plant resin from various botanical sources.

Introduction

Amber is a fossilized plant resin from various botanical sources and of different geological ages, ranging from the Carboniferous to the Pliocene, although it is particularly frequent in the Cretaceous and in the Eocene to Miocene. The term “amber” is used most commonly as a synonym for fossil resin of every provenance, geological, and palaeobotanical source. A more reductive meaning of amber has been considered, referring only to *succinite*, the mineralogical species occurring in the Baltic coast deposits and neighboring localities containing significant amounts of succinic acid (up to 8%). However, most commonly, *amber* and *fossil resin* are the terms used interchangeably for indicating macroscopic material (Anderson and Crelling, 1995; Langenheim, 2003). Another term used by coal geologists for fossil resins is *resinite*, which is a microscopic material often found in coal maceral. Amber, fossil resin, and resinite, according to Anderson and Crelling (1995) should therefore be considered “solid, discrete organic material found in coals and other sediments as macroscopic or microscopic particles, which are derived from the resins of higher plants.”

The term amber derives from the Arabic word *anbar*, which was first used to indicate *ambergris* (a waxy substance secreted by the sperm whale, used in perfumery as a fixative) and then also fossil resin, both natural products with the common feature of being carried ashore by sea waves. The Romans called amber *succinum* (from *succus*, literally “juice,” “sap”). The ancient Greek name for amber is *elektron*, that means “shining thing,” a term which was related to the Sun God *Elektor* (the awakener), and the Moon, called *Elektris* (Stoppani, 1886). The modern term *electron* was coined in 1891 by the Irish physicist George Johnstone Stoney, using the Greek word for amber because static electricity could be generated on the surface of rubbed amber. The German word *Bernstein* (or *Börnstein*), the Dutch *Barnsteen*, and the Swedish *bärnsten* mean “burning stone” because amber may burn when exposed to flame.

Geological names are often attributed to fossil resins on the basis of the locality of discovery or of the discoverer, and these names are not based on specific knowledge of the composition; however, they are often used and also quoted in the scientific literature as common names. For example, *Simetite* is for amber collected in Sicily (Italy) near the Simeto river, *Burmite*, for amber found in Burma (Myanmar), and *Rumanite* for that found in Romania; *Beckerite* and *Stantienite* were named for Becker and Stantien, two developers of amber dredging and mining operations in the Samland region in the 1800s. Over a hundred of different fossil resins have been described, so far.

Fossil resins are considered the archetype of a “chemical fossil” (chemical evidence of life processes preserved in the fossil record), and besides their property of

preserving embedded organisms, they can also maintain particular details of their original composition better than any other sedimentary material.

Amber has been known by humans since prehistorical times and most bizarre hypotheses about its origin and composition have been formulated. In the antiquity amber has been considered even as produced by the rays of the Sun (Pliny the Elder, Book 37: *Nicias solis radiorum succum intellegi voluit hoc*) and that was not such a wrong idea, since amber, as a resin of ancient trees, is a metabolite of plants, originated from products of photosynthesis, that is, from the energy of the Sun.

Amber composition and formation

Several different parameters can play relevant roles in amber composition and consequently, they all should be considered in the study and comparison of different amber samples. These are for example:

1. *Original environment*: temperature, insolation, and climate influence the resin composition before it is embedded in the sediment (biostratonomic processes);
2. *Age*: complex chemical arrangements occur with time; in general, low molecular weight components disappear with increasing age;
3. *Plant source*: resin produced by different plants exhibit different chemical composition;
4. *Diagenetic history*: following the embedding in the sediment, resin maturation is affected by temperature, pressure and permeating fluids which can modify the chemical composition and the physicochemical properties of fossil resin;
5. *Alteration processes after amber mining* (of relevance especially in archaeological context): direct sunlight and exposition to air and heat may change the color and physical properties (and, consequently, the chemical composition) of the sample.

Resins consist of secondary components of plants, that is, chemicals occurring only in some groups of plants, without an apparent role in primary physiological or metabolic pathways. Most natural resins are derived from *terpenes*, a large and varied class of hydrocarbons, which are chemicals composed by structures based on the isoprene unit (C_5H_8) (Figure 1). The basic molecular formula of terpenes can be expressed as multiples of isoprene, $(C_5H_8)_n$, where n is the number of linked isoprene units. The isoprene units can link together “head to tail” to form linear chains, or alternatively they can arrange to form rings. The overall terpene structure undergoes oxidation or rearrangement of the carbon skeleton, producing compounds, which are generally indicated as *terpenoids* or *isoprenoids*. Mono-, sesqui-, di-, and tri-terpenoids are polymers formed by two, three, four, and six isoprene units, respectively.

The biosynthesis of resins starts from simple molecules, namely mevalonic acid, which can be considered the precursor of isoprene units. Photosynthetically

produced carbohydrates are broken down to give pyruvate, which represents the basis for the synthesis of mevalonic acid. Mevalonic acid is converted into the activated form of isopentenyl pyrophosphate, which gives origin to geranyl pyrophosphate (C₁₀), the basis for the monoterpene synthesis, or can further undergo condensation into farnesyl pyrophosphate (C₁₅) for the production of sesquiterpenes, or geranyl-geranyl pyrophosphate (C₂₀), which yields diterpenes and tetraterpenes, or squalene (C₃₀), which is the basis of triterpenes (Figure 2).

Fluid resins, after their exudation from plant, are characterized by a large volatile fraction, up to 50%, mainly constituted by monoterpenes and sesquiterpenes, while the nonvolatile fraction is composed of di- and tri-terpene acids (carboxylic acids with double bonds and functional groups), with alcohols, aldehydes, and esters. The volatile components of the resins are mainly involved in the defensive role of the resin against pathogens and insects. Evaporation of volatile components, following polymerization of the remaining nonvolatile constituents, mainly presenting dienic functions, causes the hardening of resin, which, if allowed to be embedded in appropriate sediment, poses the basis for transformation into a fossil resin.

Amber, Figure 1 The basic isoprene unit (C₅H₈).

Diterpenoid resins, mainly composed of diterpene acids (C₂₀), are produced by gymnosperms (conifers) and angiosperms (mostly in the Leguminosae family), and they are particularly prone to polymerization and thus being preserved during fossilization into amber.

Gymnosperm diterpenes are mainly represented by diterpene acids of the abietane, pimarane, and labdane types (Figure 3). Abietane- and pimarane-type diterpene acids, such as abietic and pimaric acids, abundant in the Pinaceae family, tend to remain unpolymerized; on the contrary, labdane-type acids (e.g., agathic and communic acids, common in the Cupressaceae family), easily polymerize thanks to conjugated diene compounds (Langenheim, 2003). Resins of the Araucariaceae family may contain all three diterpene groups.

Also the nonvolatile fraction of angiosperm resins, for example, from the genus *Hymenaea* of the Leguminosae (Fabaceae) family, which yields copal, is constituted by diterpenes of the labdadiene group. Resins from other angiosperms, such as Dipterocarpaceae, contain mainly triterpenes.

Therefore, resins containing particular diterpenes, such as abietic acid, cannot form amber *sensu stricto* because the constituent does not contain functional groups that could lead to a cross-linked polymer (Beck, 1999). Also triterpenoid resins (C₃₀), which are mainly produced by broad-leaved trees, generally do not polymerize.

The process of polymerization and resin hardening starts just after resin exudation, and involves free radical mechanisms, which are initiated by exposure to sunlight and air (Langenheim, 2003). Initial polymerization can

Amber, Figure 2 Biosynthesis of terpenoid resins from mevalonate (adapted from Langenheim, 1969).

Amber, Figure 3 Chemical structure of major conifer resin components. Left column presents the general skeleton, and right column, an example of specific compounds (for further details, see Langenheim, 2003).

occur involving the terminal groups of a side chain in the molecule of terpenoids, mainly diterpenes with a labdanoid structure (unsaturated labdatriene acids and alcohols, and biformene), leading to the formation of a general polymeric structure (Anderson et al., 1992; Clifford and Hatcher, 1995; Clifford et al., 1997) (Figure 4). As a complex mixture, amber contains also nonpolymerizing compounds such as succinic acid in succinite, or monoterpenes, which are trapped (cross-linked) into the polymer network (Clifford and Hatcher, 1995; Clifford et al., 1997) and function as plasticizers.

Formation of amber occurs through the process of “maturation,” which is defined as the progressive changes of the resin occurring after the hardening and burial into the sediment, due to diagenetic and catagenetic processes. The chemical reactions in maturation of the resin to yield fossil resin include cross-linking, isomerization, and cyclization (Clifford and Hatcher, 1995; Clifford et al., 1997). One typical reaction in polylabdanoid fossil resins is the depletion of exocyclic methylenes (Figure 4) in the C8–C17 double bond of the molecule, and the formation of intramolecular cyclization. The modification of amber structure during its maturation leads to a progressive loss of unsaturated bonds, a decrease in functionalized groups and an increased proportion of aromatized groups (Grimalt et al., 1988).

Although the degree of resin maturation is dependent on the age of the resin, the rate at which this process occurs depends on several geological conditions, including the thermal history of the sample (Anderson et al., 1992) and on the structure and resin composition (Langenheim, 2003). Although a certain direct correlation between resin maturation and the age has also been demonstrated, by means of thermal analysis (Ragazzi et al., 2003), maturity and age cannot always be directly linked, since chemical transformation of resin increases at higher temperatures, and therefore the geothermal variable should be considered. Other physicochemical properties of amber, such as hardness and solvent solubility, may suggest the degree of maturation (Poinar, 1992; Rodgers and Currie, 1999; Langenheim, 2003; Ragazzi et al., 2003).

An alternative approach to define the age of a resin was proposed by Anderson (1997) on the basis of carbon-14 content. Resins that are older than the detection limit of carbon-14, that is, at about 40,000 years, have been considered *fossil resins*, and their age should be determined based on the stratigraphical data of the embedding sediment. Resins of age between 40,000 and 5,000 years are considered *subfossil*, while resins between 5,000 and 250 years are *ancient resins*, and those younger than 250 years are considered as *modern* or *recent*. This

Amber, Figure 4 Schematic representation of the polymeric structure in polylabdanoid fossil resins and of the maturation process (adapted from Clifford and Hatcher, 1995; Clifford et al., 1997).

terminology should be preferred to that referring to “young amber” or “copal,” which is often misleading with respect to the age of the sample.

Physicochemical characteristics of amber

Most amber pieces are minute ranging from millimeter to centimeter size. Resin pieces may be found preserved in their original shape as solidified in the amber forest (e.g., drops, elongate stalactites, lumps with a flattened side which was attached to the bark or to other surfaces). Fossil resin is sometimes still attached to fossil wood, or even *in situ* in wood or twigs which can help to identify the amber-bearing trees of a particular deposit. Amber pieces are more or less rounded after being transported and redeposited.

Amber has been extensively investigated under the physicochemical aspect. The relative hardness according to Mohs’ scale is 2–2.5 (corresponding to 199–290 MPa) for most types of amber, indicating that it is slightly harder than gypsum and that it is possible to scratch the surface with calcite or copper. The specific

gravity, that is, the ratio of the density of a substance to the density of water, ranges from about 0.96–1.12. For this reason most amber is nearly floating in sea water (specific gravity of the Baltic sea water is very low, about 1.005) and it sinks to the bottom in quiet water, but it can easily be carried along by disturbed water and washed ashore. Because of its low density, amber floats on a salt solution (about 15 g of NaCl/100 ml), while several types of plastic, often used as amber imitation, sink due to their higher density (e.g., the phenolic plastic bakelite, which has a specific gravity of about 1.4). Amber has resinous luster, and might appear translucent or opaque. Its refractive index ranges between 1.539 and 1.545. The color of translucent amber varies from a honey-like yellow and yellow-orange to light and dark red; the latter color is often caused by weathering. Rare specimens of blue (e.g., some Dominican amber) and green (e.g., some Mexican amber) samples have been found. Resins may be opaque because of microscopic bubbles or tiny detritus particles. Sometimes, densely arranged filaments of bacteria and fungi

that grew into the resin in its liquid stage cause opacity of the outer parts of resin pieces (Figure 5). If exposed to ultraviolet light, amber often produces fluorescence of blue, yellow, or green color. When amber is heated, it becomes soft at 150–180°C and decomposes around 280–300°C, emitting fumes with aromatic odor. After touching amber with a hot needle (hot point test), it produces smoke and burnt-resinous odor; this method is empirically used to distinguish between amber and plastic or copal. Exposed to a flame, amber burns easily. Amber is insoluble in water, and partly soluble in organic solvents,

such as diethyl ether, acetone, and dichloromethane, as well as in mixtures of turpentine oil and acetone. After applying a drop of solvent to the surface, recent resins (copal) or plastic are readily dissolved and the surface becomes sticky, while amber (polymerized fossil resin) is unaffected. Although resin is macroscopically amorphous, some of its constituents may form microscopic drop- or bubble-like and elongated microstructures. Some of these “pseudoinclusions” may resemble enclosed microorganisms but can be distinguished by their variable size and shape and by the absence of diagnostic surface features (Figure 6).

Chemical analyses and classification of amber

Since early chemical investigations in the nineteenth century, amber has been identified as being composed of carbon, hydrogen, and oxygen. It is not possible to indicate a univocal composition formula of amber since it is an amorphous, noncrystalline material. The composition of different types of amber, as a result of elemental analysis, has been indicated approximately in the following range: carbon 75–87%, hydrogen 8.5–11%, oxygen 5–15%, with traces of sulfur (up to 1.7%) and other elements (Kosmowska-Ceranowicz, 1984; Ragazzi et al., 2003).

Since amber is mostly insoluble in organic solvents, a complete characterization of its chemical composition has been obtained using the total solid sample, by means of specific analytical techniques that have become available, such as infrared spectroscopy (IRS), pyrolysis-gas chromatography/mass spectrometry (Py-GC/MS), and nuclear magnetic resonance (NMR) spectroscopy.

Amber, Figure 6 Pseudoinclusions in Cenomanian amber from Fourtou in the French Pyreneans (photograph by Alexander R. Schmidt).

Infrared spectroscopy of powdered samples, since the first application in the study of fossil resins (Beck et al., 1964), has become one of the main techniques for obtaining structural information and identification of amber from different origins (Kosmowska-Ceranowicz, 1999). Infrared spectra allow to define the fingerprinting of any fossil resin, and in particular it has been successful as diagnostic for Baltic amber, observing the presence of the characteristic Baltic shoulder in the 1,150–1,260 cm^{-1} region of the spectrum, attributed to the absorption of ester groups, in particular esterified succinic acid. It is noteworthy that the free succinic acid levels in Baltic amber range between 50 and 400 ppm (Tonidandel et al., 2009), despite the high total succinic acid content of 1–8%.

Anderson et al. (1992; also Anderson and Crelling, 1995), on the basis of various physicochemical methods, mainly Py-GC/MS, proposed a classification of fossil resins into five main classes:

Class I	The macromolecular structures are derived from polymers of primarily labdanoid diterpenes, which include labdatriene carboxylic acids, alcohols, and hydrocarbons
Ia	Derived from/based on polymers and copolymers of labdanoid diterpenes with regular [1S, 4aR, 5S, 8aR] configuration, including communic acid, communol, and succinic acid; example: succinite (Baltic amber)
Ib	Derived from/based on polymers and copolymers of labdanoid diterpenes with regular [1S, 4aR, 5S, 8aR] configuration, often including communic acid, communol, biformene, but not succinic acid; example: New Zealand's fossil kauri resin
Ic	Derived from/based on polymers and copolymers of labdanoid diterpenes with enantio [1S, 4aS, 5R, 8aS] configuration, including ozic acid, ozol, and enantio biformenes; examples: Mexican and Dominican amber, African resinates
Class II	Derived from/based on polymers of bicyclic sesquiterpenoid hydrocarbons, especially cadinene, and related isomers; examples: Utah and Indonesian amber
Class III	Natural (fossil) polystyrene; example: some New Jersey amber, Siegburgite from Germany
Class IV	Nonpolymeric, incorporating sesquiterpenoids based on the cedrane carbon skeleton; example: Moravian amber from the Czech Republic
Class V	Nonpolymeric diterpenoid carboxylic acid, especially based on abietane, pimarane, and isopimarane carbon skeletons; example: Highgate copalite and other retinites in European brown coals

The high-resolution NMR spectra of the carbon nuclei in powdered samples provided detailed information on the types of carbon functionality in the fossil resin, over the entire range of resonances, indicating the presence of

saturated carbons (resonances 0–100 ppm), unsaturated carbons such as alkenic and aromatic (resonances 100–160 ppm), and carbonyl groups (resonances above 160 ppm) (Lambert and Frye, 1982). Using NMR, comparative analysis of samples from different origin permitted to distinguish four major groupings (Group A through D) of fossil resins (Lambert and Poinar, 2002), in good agreement with Anderson's et al. classification based on Py-GC/MS.

Age, global occurrence, and botanical origin of amber

Amber might be found on every continent but most amber deposits have been discovered in the northern hemisphere, so far. A few ambers are known from South America, Africa, Australia, and New Zealand. Many new Mesozoic and Cenozoic amber localities have been described in the last decade (see Poinar, 1992; Grimaldi, 1996; Krumbiegel and Krumbiegel, 2005, for age and global occurrence of ambers).

A few resins were reported from the Carboniferous of Europe and the USA (Bray and Anderson, 2009). The first conifers which produced significant amounts of resin appeared in the Carnian stage of the late Triassic (about 220 million years ago). Remarkable amounts of small Triassic amber pieces have been found in the petrified forests of Arizona (Litwin and Ash, 1991), in the Molteno Formation of Lesotho (Ansorge, 2007) and the Heiligkreuz-Santa Croce Formation of the Italian Dolomites (Roghi et al., 2006, Figure 7). The latter is the oldest fossiliferous amber containing various microorganisms (Schmidt et al., 2006, see Figure 8). The Jurassic is particularly poor in amber and just few samples have been reported from the late Jurassic age of Portugal, Denmark (Bornholm), Germany, and Thailand.

The oldest Cretaceous ambers come from the Wealden Formation of southern England (Nicholas et al., 1993) and from the Kirkwood Formation of South Africa (Gomez et al., 2002), both being Valanginian in age. The most important fossiliferous Cretaceous ambers are (1) the *Middle East ambers* from Lebanon, Israel, and Jordan, ranging from the Hauterivian to the Aptian, (2) the Aptian–Albian *Álava amber* from Peñacerrada in the Basque county of northern Spain, (3) the *Siberian amber* from the Albian to Santonian of the Taimyr Peninsula, (4) the Albian–Cenomanian *ambers from Charente and Charente-Maritime* in southwestern France (see Perrichot et al., 2007, for these newly discovered ambers), (5) the *Burmese amber* from Myanmar which is Albian in age (Grimaldi et al., 2002; Cruickshank and Ko, 2003), (6) the *Atlantic coastal plain ambers* of the USA which comprise several localities of various Upper Cretaceous ages from Maryland and New Jersey to South Carolina, and (7) the Upper Cretaceous *Canadian amber* (Cedar Lake in Manitoba and other localities). Further remarkable Cretaceous resins come from Alaska, from several Albian to Coniacian localities in Japan, and from

Amber, Figure 7 Triassic amber drop from the Italian Dolomites (photograph by Guido Roghi, *Nature*, 444, 835, 2006). The piece is about 3 mm in length.

Amber, Figure 8 Shell of a testate amoeba enclosed in Triassic amber from Italy. This shell is 35 μm in size and morphologically identical to the modern species *Centropyxis hirsuta* (photograph by Alexander R. Schmidt, *Nature*, 444, 835, 2006).

the Aptian age of Golling in Austria, but these ambers yield few fossils.

Cenozoic ambers are largely Eocene to Miocene in age, and some deposits already produced tons of resin. The most well-known fossil resin is the *Baltic amber* which

can be found in the Baltic sea area (especially along the coast of Russia and Poland) in Eocene sediments, washed ashore and also as glacial erratic. The sediments bearing the Baltic amber are considered to be 38–47, some up to 55 million years old (Ritzkowski, 1999). Other fossiliferous Eocene ambers come from the *Paris Basin* in France (50–55 million years old; Nel et al., 1999), from Vastan (Gujarat) in western India (52 million years old; Alimohammadian et al., 2003) and from Fu Shun in the Chinese Liaoning province. The Bitterfeld amber from a coal mine near the city of Bitterfeld in central Germany is uppermost Oligocene in age (24 million years old, see Wimmer et al., 2006) and also produced a plethora of inclusions, mainly arthropods (Knuth et al., 2002). The most fossiliferous Cenozoic New World ambers come from the Dominican Republic and from Chiapas in Mexico (see Poinar, 1992). Recent studies suggest a Miocene age (15–20 million years old) for these Caribbean ambers (Iturralde-Vinent and MacPhee, 1996; Solórzano Kraemer, 2007). Further fossiliferous Miocene ambers were found in western Amazonia in Peru, and in Sicily and Borneo.

Representatives of various gymnosperm and angiosperm families have produced resin in the Earth's history (see Langenheim, 2003; Krumbiegel and Krumbiegel, 2005, for overview). The Italian Triassic amber was possibly produced by members of the Cheirolepidiaceae, an extinct gymnosperm family. Among others, various representatives of the Araucariaceae (Figures 9 and 10) and Cupressaceae are considered to be resin-bearing trees in the Cretaceous. Angiosperm resins are recorded since the Eocene, for example, *Glessite* stems from Burseraceae and *Siegburgite* were produced by Hamamelidaceae. The tropical genus *Hymenaea* (Leguminosae) produced the Dominican and Mexican ambers. The main resin-bearing trees of the Baltic amber forest probably belonged to conifers of the family Sciadopityaceae, as recently suggested by Wolfe et al. (2009).

Embedding and preservation of organisms in resin

Resins are produced by plants as defensive reaction against mechanical damage (injury to the bark, fire, herbivores) and potential invasion by pathogens, such as bacteria and fungi. Also, climatic reasons and ecological disturbance have been discussed to be the reasons for extensive resin production (Henwood, 1993).

The exceptional preservation of organisms included in amber is due to the dehydration environment made possible by the resin and by natural embalming properties due to antiseptic activity of the resin constituents. Components that do not participate in polymerization of the resin, such as some diterpene resin acids (e.g., copalic acid), can remain available for the interactions with biota embedded in resin (Henwood, 1993) and contribute to the preservation even of soft-bodied inclusions. Even cell organelles such as chloroplasts of algae are sometimes well-preserved in amber (Figure 11).

Amber, Figure 9 Resinous forest of *Araucaria columnaris* growing at the coast of Maré, New Caledonia (photograph by Alexander R. Schmidt).

Amber, Figure 10 Extensive resin flows of ~30 cm length induced by fire at the bark of *Araucaria columnaris* in New Caledonia (photograph by Alexander R. Schmidt).

Extraction of ancient DNA from amber has been of particular interest in working with fossils embedded in amber, and in the early 1990s first attempts to establish methods for extraction, amplification, and sequencing of fossil

Amber, Figure 11 Preservation of chloroplasts in the conjugatophyte *Palaeozygnema spiralis* from the Cenomanian resin of Schliersee in the Bavarian Alps. The cells are ~15 μm in diameter (photograph by Alexander R. Schmidt).

DNA from amber were carried out (e.g., Cano et al., 1994; Cano and Borucki, 1995). However, critical reinvestigations suggest that the DNA obtained in these studies was modern contamination and because even the amplification of DNA from copal failed, Austin et al. (1997) concluded that resin is not predestined for the preservation of complex molecules, although morphological structures are recorded very well.

Attached to fresh sticky resin (Figure 10), organisms or parts of them are entirely covered by further resin flows. Amber inclusions are therefore usually found at the surfaces of successive resin flows in amber. Invertebrates of appropriate size, especially arthropods (e.g., diptera, hymenoptera, see Figure 12), and small plant remnants fallen onto the resin are therefore predestined for getting stuck and embedded. Arthropods, plant remnants (flowers, leaves, stellate hairs, wood, pollen, spores) and microorganisms are typical amber inclusions and sometimes, also small vertebrates (frogs, lizards) and parts of larger animals (reptile skin, feathers, hairs) are preserved. Some groups of organisms are only recorded as amber fossils, since few other fossilization processes occur in terrestrial environments which may preserve morphological structures even of soft-bodied organisms very well.

Many life forms and representatives of all trophic levels of a biocoenosis may be found in a single piece of resin: bacteria, algae as producers, protozoans, micrometazoans, molluscs, arthropods as consumers, and fungi as decomposers (Perrichot and Girard, 2009). Although many members of a biocoenosis can potentially become embedded in resin, selective embedding has been observed (Schmidt and Dilcher, 2007). Because of their motility, moving or flying arthropods have a higher probability of encountering and becoming attached to the resin. Therefore, the amount of amber inclusions of a species is not correlated with its abundance in the ancient ecosystem.

Most amber inclusions are fossils of terrestrial organisms which lived at or close to the resin-bearing trees. Much resin solidified at the forest floor, not on the bark (Henwood, 1993) and the term *litter amber* has been proposed by Perrichot (2004) for amber pieces which largely contain soil and litter-dwelling arthropods (Figure 13).

Amber, Figure 12 Hymenoptera (Scelionidae), fossilized in Lower Cenomanian amber of Fouras, Charente-Maritime, southwestern France. The inclusion is 1.8 mm in length (courtesy of Vincent Perrichot).

To find aquatic organisms in tree resin may seem to be highly unlikely but the fossil record provides amber-preserved limnetic arthropods (e.g., water beetles, water striders, crustaceans, larvae of caddisflies and mayflies) and microorganisms (e.g., algae, ciliates, testate amoebae, rotifers). Limnetic organisms may get stuck or enclosed when resin comes into contact with water or even flows into water (Schmidt and Dilcher, 2007).

Few amber inclusions of marine organisms (crustaceans, diatoms) have been reported from amber forests which grew directly at the coast (Vonk and Schram, 2007; Girard et al., 2008; see Figure 14). These organisms were probably introduced by wind or spray from beach and sea onto the resin flows in the nearby woods.

Although resin has fungicidal properties, some fungi and bacteria are able to grow into liquid resin and can therefore be found in almost every fossil resin. Usually, these filaments grow in random orientation as long as the resin is liquid. Growth stops when the resin solidifies and the filiform inclusions become well-preserved in the resin. Resinicolous fungi such as ascomycetes of the Mycocaliciales are adapted to their special substrates and are also able to grow on fresh resin. Therefore, they may be found in places where herbivore insects induce long-term resin flows (Rikkinen, 1999; Rikkinen and Poinar, 2000).

Resin which dried at the bark is exposed to the air, and processes of weathering and degradation start rapidly. Long-time preservation of resins and its inclusions and

Amber, Figure 13 *Marchandia magnifica*, a mole cricket from Albian amber from southwestern France. It is 3.8 mm in length (photograph by Vincent Perrichot, courtesy of Elsevier/ Academic Press, *Cretaceous Research*, 23, 307–314, 2002).

Amber, Figure 14 Two frustules of a marine diatom of the genus *Hemiaulus* enclosed in a piece of amber from a coastal Cretaceous forest from Archingeay in south-western France. The cells are ca 40 μm in size (photograph by Alexander R. Schmidt).

formation of amber therefore generally needs redeposition into marine sediments or at least a cover by sediment layers to stop processes of oxidation.

Summary

Amber is fossilized plant resin, which is largely found in the Cretaceous and in the Eocene to Miocene when various representatives of gymnosperms and angiosperms produced considerable amounts of resin. After exudation from plants, the volatile components evaporate and the remaining nonvolatile constituents polymerize which leads to the hardening of the resin. Formation of amber occurs through the process of “maturation,” which is defined as the progressive changes of the resin occurring after the hardening and embedding into the sediment. The chemical reactions in the maturation of the resin to yield fossil resin include cross-linking, isomerization, and cyclization. Several different parameters can play relevant roles in amber composition, such as original environment, age, plant source, diagenetic history, and also alteration processes after amber mining. Inclusions of many life forms may be found in amber, although selective embedding has been observed. The taphocoenosis in a piece of amber may potentially contain organisms of different habitats such as tree bark, soil and litter, freshwater ponds, and littoral.

Anaerobic oxidation of methane (AOM): microbially mediated oxidation of methane to CO₂ by electron acceptors other than oxygen.

Introduction

Methane is the most abundant hydrocarbon in the atmosphere, and an important greenhouse gas (see *Methane, Origin*). A great deal of research has focused on the cause and climatic consequences of the variation in fluxes of methane to the atmosphere, throughout the Earth's history. Three key functional groups of microbial organisms play a central role in regulating the fluxes of methane on the Earth, namely the methanogens, the aerobic methanotrophic bacteria, and the more recently discovered anaerobic methanotrophic archaea (ANME). It is estimated that AOM is a major sink for methane on the Earth, and of similar relevance as its photooxidation in the atmosphere (Hinrichs and Boetius, 2002; Reeburgh, 2007).

Today, most methane is produced by methanogenesis, i.e., the final step in the fermentation of organic matter taking place in soils, wetlands, landfills, rice fields, freshwater and marine sediments, as well as in the guts of animals. Almost all of the methane produced in ocean sediments is consumed by AOM within the sulfate penetrated seafloor zones. Hence, the ocean does not contribute significantly to the atmospheric methane budget (<2%; Reeburgh, 2007). The first evidence for the removal of methane within anoxic sediments and seawaters came from

geochemical observations in the 1970s and 1980s (Reeburgh, 1969, 1976; Barnes and Goldberg, 1976; Martens and Berner, 1977). The involvement of sulfate as terminal electron acceptor was demonstrated by radiotracer measurements of methane oxidation and sulfate reduction in parallel incubations of undisturbed sediment samples (Iversen and Jørgensen, 1985). Field observations and experiments led to the hypothesis of a coupled mechanism, in which both methanotrophic archaea and sulfate-reducing bacteria (SRB) could profit from AOM, despite the generally low thermodynamic energy yield from this reaction (Hoehler et al., 1994). Finally, consortia of such microorganisms were detected in sediments from methane seeps, and the substantial depletion of their specific biomarkers in the stable carbon isotope ¹³C suggested that methane or a methane-derived compound is used as carbon source by these organisms (Hinrichs et al., 1999; Boetius et al., 2000; Orphan et al., 2001b). Till recently, all known anaerobic methanotrophs were clades related to the methanogenic Euryarchaeota termed ANME. In 2008, bacteria were found capable of oxidizing methane anaerobically with nitrate (Ettwig et al., 2008; 2010). In the past decade, much has been learned about the distribution, activity, and physiology of the ANME, however, not a single member of these groups has been obtained in culture and the biochemical functioning of AOM remains unknown.

The process of AOM

The AOM with sulfate as the final electron acceptor according to

is the major sink of methane in the oceans and hence a significant process in the global carbon cycle and methane budget (Reeburgh, 2007). Aggregated methanotrophic archaea (ANME) and SRB are assumed to act syntrophically (Hoehler et al., 1994; Hansen et al., 1998; Hinrichs et al., 1999; Boetius et al., 2000) where the archaeal partner activates and metabolizes methane, leading to an intermediate that is scavenged as electron donor by the sulfate-reducing partner. So far, there is no evidence for the involvement of extracellular intermediates such as hydrogen, formate, or acetate (Nauhaus et al., 2002; Boetius et al., 2008). The process of AOM with sulfate has been maintained in vitro in the laboratory and investigated with respect to substrate-product stoichiometry and dependence on pressure, temperature, and a variety of other environmental factors (Nauhaus et al., 2002, 2005, 2007; Girguis et al., 2003, 2005). The ANME doubling time was reported to be approximately 7 months, and the molar growth yield of AOM was 0.6 g cell dry weight (mol CH₄ oxidized)⁻¹. Corresponding to this estimate, only 1% of the consumed methane is channeled into the ANME biomass

Anaerobic oxidation of methane (AOM): microbially mediated oxidation of methane to CO₂ by electron acceptors other than oxygen.

Introduction

Methane is the most abundant hydrocarbon in the atmosphere, and an important greenhouse gas (see *Methane, Origin*). A great deal of research has focused on the cause and climatic consequences of the variation in fluxes of methane to the atmosphere, throughout the Earth's history. Three key functional groups of microbial organisms play a central role in regulating the fluxes of methane on the Earth, namely the methanogens, the aerobic methanotrophic bacteria, and the more recently discovered anaerobic methanotrophic archaea (ANME). It is estimated that AOM is a major sink for methane on the Earth, and of similar relevance as its photooxidation in the atmosphere (Hinrichs and Boetius, 2002; Reeburgh, 2007).

Today, most methane is produced by methanogenesis, i.e., the final step in the fermentation of organic matter taking place in soils, wetlands, landfills, rice fields, freshwater and marine sediments, as well as in the guts of animals. Almost all of the methane produced in ocean sediments is consumed by AOM within the sulfate penetrated seafloor zones. Hence, the ocean does not contribute significantly to the atmospheric methane budget (<2%; Reeburgh, 2007). The first evidence for the removal of methane within anoxic sediments and seawaters came from

geochemical observations in the 1970s and 1980s (Reeburgh, 1969, 1976; Barnes and Goldberg, 1976; Martens and Berner, 1977). The involvement of sulfate as terminal electron acceptor was demonstrated by radiotracer measurements of methane oxidation and sulfate reduction in parallel incubations of undisturbed sediment samples (Iversen and Jørgensen, 1985). Field observations and experiments led to the hypothesis of a coupled mechanism, in which both methanotrophic archaea and sulfate-reducing bacteria (SRB) could profit from AOM, despite the generally low thermodynamic energy yield from this reaction (Hoehler et al., 1994). Finally, consortia of such microorganisms were detected in sediments from methane seeps, and the substantial depletion of their specific biomarkers in the stable carbon isotope ¹³C suggested that methane or a methane-derived compound is used as carbon source by these organisms (Hinrichs et al., 1999; Boetius et al., 2000; Orphan et al., 2001b). Till recently, all known anaerobic methanotrophs were clades related to the methanogenic Euryarchaeota termed ANME. In 2008, bacteria were found capable of oxidizing methane anaerobically with nitrate (Ettwig et al., 2008; 2010). In the past decade, much has been learned about the distribution, activity, and physiology of the ANME, however, not a single member of these groups has been obtained in culture and the biochemical functioning of AOM remains unknown.

The process of AOM

The AOM with sulfate as the final electron acceptor according to

is the major sink of methane in the oceans and hence a significant process in the global carbon cycle and methane budget (Reeburgh, 2007). Aggregated methanotrophic archaea (ANME) and SRB are assumed to act syntrophically (Hoehler et al., 1994; Hansen et al., 1998; Hinrichs et al., 1999; Boetius et al., 2000) where the archaeal partner activates and metabolizes methane, leading to an intermediate that is scavenged as electron donor by the sulfate-reducing partner. So far, there is no evidence for the involvement of extracellular intermediates such as hydrogen, formate, or acetate (Nauhaus et al., 2002; Boetius et al., 2008). The process of AOM with sulfate has been maintained in vitro in the laboratory and investigated with respect to substrate-product stoichiometry and dependence on pressure, temperature, and a variety of other environmental factors (Nauhaus et al., 2002, 2005, 2007; Girguis et al., 2003, 2005). The ANME doubling time was reported to be approximately 7 months, and the molar growth yield of AOM was 0.6 g cell dry weight (mol CH₄ oxidized)⁻¹. Corresponding to this estimate, only 1% of the consumed methane is channeled into the ANME biomass

(Nauhaus et al., 2007). Further steps toward an understanding of the metabolic pathway were the purification of a candidate enzyme (Ni-protein I) that may catalyze methane activation in a reverse terminal methyl-coenzyme M reductase reaction (Krüger et al., 2003) and genome-based observations of nearly all genes involved in methane production present in one specific ANME type (Hallam et al., 2004; Meyerdierks et al., 2009) both supporting the hypothesis that ANME carry out AOM by reverse methanogenesis.

Anaerobic methanotrophs

Discovery of ANME

Hinrichs et al. (1999) discovered a new archaeal group in sediments from a methane seep in the Eel River basin off California, together with characteristic archaeal lipid biomarkers strongly depleted in ^{13}C , indicating that methane must be the carbon source (Hinrichs et al., 1999). The dominant archaeal group was defined as ANME-1 and a second major group associated with was identified later as ANME-2 (Orphan et al., 2001a). Boetius et al. (2000) provided the first microscopic evidence for a syntrophic association of ANME archaea and SRB (Boetius et al., 2000). In both studies specific archaeal lipid biomarkers, i.e., archaeol, hydroxyarchaeol, crocetane, and pentamethylcosane (PMI), and bacterial lipid biomarkers common for SRB, i.e., *iso*- and *anteiso*- C_{15} fatty acids, were strongly depleted in ^{13}C . The first direct link between the identity and metabolic activity of ANME was provided by using a combination of ion microprobe mass spectrometry (SIMS) and fluorescence in situ hybridization (FISH) (Orphan et al., 2001b, 2002). These experiments confirmed the extreme ^{13}C depletion in the aggregate biomass, as predicted from the biomarker extractions. In 2006, a third archaeal ANME group, ANME-3, was discovered at the submarine mud volcano Haakon Mosby in the Barents Sea (Niemann et al., 2006b). Recently, a new clade of ANME-associated archaea (AAA) was identified in a bioreactor inoculated with sediments from a Dutch canal, but their relevance in freshwater and marine sediments remains unknown (Raghoebarsing et al., 2006; Knittel and Boetius 2009).

Diversity and morphology of ANME organisms

All yet known ANMEs are Euryarchaeota, and they form clusters distantly or closely related to the orders *Methanosarcinales* and *Methanomicrobiales*, which comprise a major part of the cultivated methanogens (Figure 1a).

The phylogenetic distance between the three ANME groups is large with 75–92% sequence similarity. Thus, members of ANME-1 and ANME-2 certainly belong to different orders or families, which have apparently similar physiological properties, i.e., the capability to oxidize methane anaerobically.

ANME-1 cells have a typical rectangular morphology and are autofluorescent under UV light, a feature characteristic for methanogenic archaea containing coenzyme F_{420} . ANME-1 archaea most often occur as single cells (Figure 2a) or in chains of two to four cells. In the Black Sea, “mat-type” associations of ANME-1 archaea and sulfate-reducing partners (Figure 2b) or ANME-1 and ANME-2 archaea (Figure 2c) form microbial mats (Michaelis et al., 2002; Knittel et al., 2005; Treude et al., 2007).

ANME-2 archaea belong to the order *Methanosarcinales*, but sequence similarity to cultivated representatives is below 90%. Similarity between subgroups, ANME-2a to ANME-2c, varies with an inter- and intra-group similarity of 75–90% and 90–100%, respectively. Diverse forms of associations between ANME-2 and their partner bacteria have been found (Figure 2d–k). Single ANME-2 cells were also reported (Figure 2d, l; Treude et al., 2007) as aggregated ANME-2 without any partner (Figure 2m, n; Orphan et al., 2002; Treude et al., 2007). In addition to the differences in phylogenetic origin, the two subpopulations ANME-2a and -2c could be distinguished from each other by their aggregate morphology. In general, ANME-2a/*Desulfosarcina* (DSS) aggregates represent the “mixed-type.” Here, archaea and SRB are completely mixed and the aggregates are not always spherical (Figure 2f–k). Typical ANME-2c/DSS aggregates represent the common “shell-type” with an inner core of ANME-2 which is partially or fully surrounded by an outer shell of SRB (Figure 2o–x). Sometimes SRB grow into the inner ANME-2c core, but they do not seem to mix completely (Figure 2u–w; Knittel et al., 2005). Microscopical analysis of a growing ANME-2 population showed that population growth occurred both as an increase in the number as well as in size of the shell-type consortia (Nauhaus et al., 2007). Starting from a few archaea and SRB cells, consortia seem to develop from smaller sized consortia to big aggregates of up to 100,000 cells (Holler and Knittel, unpublished data). Larger consortia separate evenly into two or unevenly into more aggregates when SRB grow into the archaeal colonies. The average diameter of consortia is 3–5 μm in situ with the smallest detected aggregate consisting of one ANME and one SRB cell and the largest 20 μm (Boetius et al., 2000; Knittel et al., 2005; Lösekann et al., 2007). Even much larger aggregates have been observed in enrichment cultures with >40 μm in diameter (Nauhaus et al., 2007; Holler, unpublished data). After reaching a specific size they appear to burst, releasing single cells into the environment (Figure 2ab).

The ANME-3 clade also belongs to the order *Methanosarcinales* and is closely related to cultivated species of the genus *Methanococcoides* with 95% 16S rRNA sequence similarity (Figure 1a). They form shell-type aggregates with a *Desulfobulbus* population as sulfate-reducing partner, however, only very few bacterial cells are associated (Figure 2y–z, aa).

Anaerobic Oxidation of Methane with Sulfate, Figure 1 (Continued)

Identification of ANME by methyl coenzyme M reductase gene phylogeny

The first genomic and proteomic analyses of sediments and microbial mats naturally enriched in the ANME biomass revealed a nickel protein similar to methyl coenzyme M reductase (MCR) as well as genomic fragments coding for nearly all genes typically associated with methane production. Based on these observations, earlier hypotheses on the role of reverse methanogenesis in archaea (Zehnder and Brock, 1979, 1980; Hoehler et al., 1994) appeared in a new light. Subsequently, molecular studies were conducted targeting the enzyme MCR, which catalyzes the terminal step in biogenic methane production (Shima and Thauer, 2005). Investigations have revealed a remarkably high phylogenetic diversity within *mcrA* genes among ANME archaea (Hallam et al., 2003; Inagaki et al., 2004, 2006a; Dhillon et al., 2005; Kelley et al., 2005; Alain et al., 2006; Lloyd et al., 2006; Nunoura et al., 2006; Lösekann et al., 2007) which have been classified into four subgroups (Hallam et al., 2003; Lösekann et al., 2007), group a–b (ANME-1), group c–d (ANME-2c), group e (ANME-2a), and group f (ANME-3) (Figure 1b). These groups are all distinct from those formed by methanogens. ANME *mcrA* gene phylogeny appears to be partially phylogenetically congruent to the 16S rRNA gene (Figure 3; Hallam et al., 2003; Nunoura et al., 2006; Lösekann et al., 2007). Quantification of specific ANME groups based on their *mcrA* gene abundance is now an alternative method to 16S rRNA based FISH to study distributional patterns of anaerobic methanotrophs in AOM zones (Nunoura et al., 2006).

Identification of ANME by their specific lipid biomarkers

Another molecular method, which has been crucial in the investigation of the natural distribution of ANME populations, is the identification of specific lipid biomarkers (see *Biomarkers*) and their stable carbon isotope signatures. This method can integrate phylogenetic information with function (^{13}C signatures indicating methane assimilation) and can be used for comparative analyses of community biomass. All three known ANME groups and their partner bacteria incorporate light (^{13}C -depleted) methane-derived carbon into their membrane lipids (Orphan et al., 2002; Niemann et al., 2006b). Using either naturally ^{13}C depleted methane (Nauhaus et al., 2007) or ^{13}C labeled methane as substrate (Blumenberg et al., 2004) for active populations of ANME in environmental samples have helped to identify typical membrane lipid

profiles. Crocetane is the only biomarker lipid specific for ANME, i.e., not found in methanogen cultures. Glycerol dibiphytanyl glycerol tetraethers (GDGT) were also used as indicator of ANME distribution (Schouten et al., 2003), but the ANME GDGTs appear to show some overlap with those of benthic Crenarchaeota, which often share the same niche in the seabed (Knittel et al., 2005). Recently, the biomarker approach was extended to include intact polar lipids (IPLs) which are of higher taxonomic specificity (level of families to orders) and property to select for living biomass (Sturt et al., 2004; Biddle et al., 2006; Rossel et al., 2008). Characteristic IPL molecular fingerprints have been reported for each specific ANME type: the lipids of ANME-1 archaea were dominated by diglycosidic GDGT derivatives, while IPLs of ANME-2 and ANME-3 archaea are dominated by phosphate-based polar derivatives of archaeol and hydroxyarchaeol (Rossel et al., 2008).

Bacterial partners of ANME

ANME-1 and ANME-2 archaea are usually associated with SRB of the SEEP-SRB I branch, subgroup a, of the *Desulfosarcina/Desulfococcus* (DSS) group (Figure 2; Schreiber et al., 2010).

These SRB are physically attached to the ANME-2 archaea, whereas ANME-1 is most often found without close physical association to other cells. The diversity within the SEEP-SRB1 cluster is high, and it is still unknown if the partners of the ANME-2a, -2b, and -2c subgroups belong to the same species. The morphology of the DSS cells varies from cocci (mostly associated with ANME-2c cells, Figure 2p–x) to rods (mostly associated with ANME-2a cells, Figure 2f–j). Other SRB have not yet been identified to be associated with ANME-1 and -2. ANME-3 archaea are most often associated with SRB of the *Desulfobulbus* branch (Figure 2), but have also been detected together with SRB of the *Desulfosarcina/Desulfococcus* group in shallow subsurface sediments of cold seeps from the Hydrate Ridge (Lösekann et al., unpublished data). Single cells of ANME-1, -2, and -3 have also been found in situ as well as in vitro enrichments, indicating that the physical association may be not obligate, but certainly the typical life mode of the anaerobic methanotrophs in most habitats.

There is also some evidence that the diversity of bacteria associated with ANME may be larger than anticipated. The analysis of ANME-2c consortia captured by whole-cell magneto-FISH showed a diversity of bacterial partners of ANME-2 far beyond the Deltaproteobacteria

Anaerobic Oxidation of Methane with Sulfate, Figure 1 Phylogenetic trees showing the affiliations of (a) anaerobic methanotrophic archaea (ANME) 16S rRNA gene sequences to selected reference sequences of the domain archaea. The tree was calculated with nearly full-length sequences (>1,300 bp) by maximum-likelihood analysis in combination with filters excluding highly variable positions. Data in colored boxes give information about the distribution and abundance of sequence retrieval and (b) ANME gene sequences coding for the alpha subunit of methyl coenzyme M reductase (*mcrA*) to selected sequences of the domain archaea. The tree was generated from deduced amino acid sequences (>247 amino acids) by neighbor-joining analysis with a 30% amino acid frequency filter. *mcrA* tree by courtesy of Lösekann. Bar, 10% estimated sequence divergence.

Anaerobic Oxidation of Methane with Sulfate, Figure 2 Epifluorescence micrographs of different ANME single cells and aggregates visualized by fluorescence in situ hybridization (FISH) or CARD-FISH. (a) Single ANME-1 cells living in a microbial mat from the Black Sea; (b) mat-type consortium formed by ANME-1 (red) and DSS cells (green); (c) aggregated ANME-1 (green) and ANME-2 cells (blue) in a microbial mat from the Black Sea; (d) single ANME-2a cells in an enrichment culture from Hydrate Ridge sediments; (e–k) mixed-type consortia of ANME-2a (red) and DSS (green) cells observed in different seep sediments; (l) single ANME-2a cells; (m) monospecific ANME-2a aggregate; (n) corresponding DAPI staining in an enrichment culture from Hydrate Ridge sediments; (o–x) shell-type consortia of ANME-2c (red) and DSS (green) cells of different sizes and structure observed in different seep sediments; (y–aa): ANME-3; (y) monospecific aggregation of ANME-3 at Haakon Mosby mud volcano, (z, aa) ANME-3/*Desulfobulbus* consortia; and (ab): DAPI staining of a large ANME-2c aggregate. Unless otherwise indicated, scale bar 10 μm.

Anaerobic Oxidation of Methane with Sulfate, Figure 3 Phylogenetic tree showing the affiliations of ANME-sulfate-reducing bacteria partner 16S rRNA gene sequences to selected reference sequences of the *Deltaproteobacteria*. The tree was calculated with nearly full-length sequences (>1,450 bp) by maximum-likelihood analysis in combination with filters excluding highly variable positions. Groups known as ANME partners are printed in boldface. Scale bar gives 10% estimated sequence divergence.

(Pernthaler et al., 2008). Lösekann et al. found evidence for ANME-3 aggregates with unidentified partners showing a mixed-type morphology in sediments from the Arctic mud volcano Haakon Mosby (Lösekann et al., 2007).

Habitats of ANME

Since their discovery, the distribution of the ANME organisms has been studied intensively, mainly based on 16S rRNA gene phylogeny. More than 1800 16S rRNA gene sequences are available now from more than 50 different marine methane seeps (Hinrichs et al., 1999; Orphan et al., 2001a; Aloisi et al., 2002; Tourova et al., 2002; Mills et al., 2003, 2004, 2005; Inagaki et al., 2004; Heijs et al., 2005, 2007; Knittel et al., 2005; Lanoil et al., 2005; Stadnitskaia et al., 2005; Arakawa et al., 2006a, b; Fang et al., 2006; Lloyd et al., 2006; Martinez et al., 2006; Niemann et al., 2006a; Nunoura et al., 2006; Reed et al., 2006; Lösekann et al., 2007), vents (Takai and Horikoshi, 1999; Teske et al., 2002; Kelley et al., 2005; Brazelton et al., 2006; Inagaki et al., 2006a), and “sulfate–methane

transition zone” (SMTZ) (Thomsen et al., 2001; Niemann et al., 2005; Parkes et al., 2007) differing in e.g., temperature, methane flux, salinity, and pH. Furthermore, the presence of ANME organisms in the water column (Black Sea; Vetriani et al., 2003; Schubert et al., 2006a) and in a terrestrial mud volcano in the Carpathian mountains (Romania; Alain et al., 2006) has also been reported. A comparison of these reports shows that globally, the two most abundant and diverse phylogenetic groups of methane-oxidizing archaea are the ANME-1 and ANME-2 clades. The distribution of ANME-2a and ANME-2c is as wide as for ANME-1, but only few sequences have been reported belonging to subgroup ANME-2b. ANME-2b, originally defined on the basis of few sequences as a separate group (Orphan et al., 2001a), now seem to be rather a subgroup of ANME-2a than a monophyletic group (Figure 1a).

Today it is known that ANME are present wherever methane and sulfate co-occur, at a wide range of environmental conditions (Knittel and Boetius, 2009). However,

usually only one specific ANME group dominates a habitat and seems to be responsible for most of the measured AOM (Knittel et al., 2005). High rates of methane oxidation, sulfate reduction, and/or sulfide production can be used as an indicator for high densities of ANME populations (Boetius et al., 2008). Continuous high fluxes of both AOM substrates methane and sulfate at mM concentrations sustain high cell densities of $>10^{10}$ ANME cells cm^{-3} in the environment and can even form some of the densest and largest cell accumulations known to exist in nature (Michaelis et al., 2002).

Seep ecosystems

Cold seeps form where tectonic or gravitational forces advect free gas, methane-rich porewater and/or mud upward into the sulfate-penetrated surface sediments and sometimes into the hydrosphere (Judd and Hovland, 2007; see *Cold Seeps*). The increased availability of dissolved methane at higher hydrostatic pressures increases the energy yield of AOM and leads to a natural enrichment of ANME populations. The products of AOM, sulfide and carbonate accumulate in the seabed, forming the typical features of cold seep ecosystems such as carbonate precipitates and high sulfide fluxes. The sulfide is oxidized chemically and microbially with oxygen, nitrate, or iron close to the seafloor surface. One of the most striking visual features of submarine cold seep ecosystems are mats of thiotrophic bacteria covering the seafloor. These mats are usually associated with high AOM rates and dense ANME communities inhabiting the underlying sediments (Sahling et al., 2002; Treude et al., 2003; Joye et al., 2004; Niemann et al., 2006b). Also, a variety of thiotrophic microbe–animal symbioses profit from AOM, such as siboglinid tubeworms and mytilid as well as vesicomyid bivalves (Sibuet and Olu, 1998). Thiotrophic mats and invertebrate symbioses may enhance the growth of ANME populations by rapidly removing the toxic endproduct sulfide, and by replenishing sulfate in the sediments (Treude et al., 2003; Cordes et al., 2005; Niemann et al., 2006b). In active cold seep sediments, AOM rates of $500\text{--}5,000\text{ nmol CH}_4\text{ cm}^{-3}\text{ day}^{-1}$ ($>2\text{ mol m}^{-2}\text{ year}^{-1}$) are reached, associated with very dense ANME populations of $>10^{10}$ cells cm^{-3} (Boetius et al., 2000; Knittel et al., 2005; Niemann et al., 2006b).

Cold seep ecosystems from Eel River Basin (Hinrichs et al., 1999; Orphan et al., 2001b), Hydrate Ridge (Boetius et al., 2000; Knittel et al., 2003, 2005), Black Sea (Thiel et al., 2001, 2003, 2007; Michaelis et al., 2002; Blumenberg et al., 2005; Reitner et al., 2005a, b; Treude et al., 2005a, 2007), Gulf of Mexico (Orcutt et al., 2005; Lloyd et al., 2006; Martinez et al., 2006), the Tommeliten and Gullfaks area in the North Sea (Wegener et al., 2008), and mud volcanoes from the Mediterranean Sea (Omorgie et al., 2008) and the Barents Sea (Niemann et al., 2006b; Lösekann et al., 2007) have been intensively studied. With the exception of cold seeps in the Black Sea (see next) most of the studies indicate a

dominance of ANME-2 or ANME-3. A prominent example is the gas hydrate bearing sediment from the Hydrate Ridge. Hot spots of ANME-2 are surface layers just above the gas hydrates with up to 10^8 aggregates cm^{-3} . Interestingly, ANME-2 subgroups revealed preferences for either *Beggiatoa* (ANME-2a) or *Calyptogenia* (ANME-2c) fields (Knittel et al., 2005) indicating that different environmental conditions select for different ANME groups.

Two seep systems are known yet where other ANMEs dominate: (1) sediments overlaying a brine pool methane seep in the Gulf of Mexico are dominated by ANME-1b archaea. Here, the ANME-1b community was found in the sulfate-methane interface, where low methane concentrations of ca. 100–250 μM are present and coexist with sulfate concentrations of ca. 10 mM; and (2) microbial mats from Black Sea cold seeps. These seeps are unique ecosystems and AOM is important both in sediments and in the water column (Pimenov et al., 1997; Wakeham et al., 2003). Tall reef-like structures composed of porous carbonates and microbial mats are found on the seafloor. These mats have been shown to mediate AOM and consist mainly of densely aggregated ANME-1 cells and SRB (Michaelis et al., 2002; Blumenberg et al., 2004, 2005; Knittel et al., 2005; Reitner et al., 2005a, b; Treude et al., 2005a, 2007). Treude et al. (2007) combined radiotracer incubations, beta-microimaging, SIMS, and CARD-FISH to locate hot spots of methanotrophy. Incorporation of ^{14}C from radiolabeled CH_4 indicated a hot spot for methanotrophy close to the mat surface associated with a dominance of ANME-1 archaea (Treude et al., 2007). The mats, however, are very heterogeneous and also provide niches for ANME-2. Black nodules from the top of the reef seem to be dominated by ANME-2 as shown by specific ^{13}C depleted lipids and FISH (Blumenberg et al., 2004). Reitner et al. found intracellular precipitation of iron sulfide (greigite) by bacteria growing in close association with ANME-2 and suggested iron cycling as an additional pathway involved in AOM (Reitner et al., 2005b).

ANME-3 archaea are commonly found at submarine mud volcanoes (Niemann et al., 2006b; Heijs et al., 2007; Lösekann et al., 2007; Omorgie et al., 2008) but also at other cold seeps (Orphan et al., 2001a; Inagaki et al., 2004; Knittel et al., 2005), hydrothermal vents (Brazelton et al., 2006), and recently in subsurface sediments (Parkes et al., 2007).

Sulfate–methane transition zones (SMTZ)

The most common ANME habitat on the Earth is the so-called SMTZ in the seabed (Thomsen et al., 2001; Ishii et al., 2004; Niemann et al., 2005, 2006a; Treude et al., 2005b; Parkes et al., 2007). SMTZ are found in all seabed horizons where the diffusive transport of methane from below and sulfate from above leads to a zone of AOM. Methane is completely consumed in the SMTZ, which may be found at decimeters to tens of meters below the seafloor (D'Hondt et al., 2004), depending on the depth

of the methane production zone, on the transport velocity of methane and sulfate and on their consumption rates. In diffusive seabed systems, the distribution of ANME is restricted to SMTZ. Population densities of ANME are low with $<10^6$ cells cm^{-3} (Niemann et al., 2005) and associated AOM rates are below $10 \text{ nmol cm}^{-3} \text{ day}^{-1}$ ($<0.04 \text{ mol m}^{-2} \text{ year}^{-1}$). The 16S rRNA gene libraries of ANME populations associated with SMTZ zones are very similar to those of cold seeps. The in situ dominance of ANME groups varies between the habitats. In SMTZ, sediments of Eckernförde Bay (German Baltic) ANME-2 archaea dominated (Treude et al., 2005b) as in the Skagerrak off the Danish coast (Parkes et al., 2007) or in a tidal sand flat of the German Wadden Sea (Ishii et al., 2004) while in the SMTZ of the Tommeliten seep area or at Hydrate Ridge ANME-1 were dominant (Niemann et al., 2005; Orcutt et al., unpublished data). Most likely, the SMTZ ANME archaea represent the seed populations for cold seep communities. It remains unknown whether SMTZ ANME possess special physiological adaptations to their energetically less favorable habitat compared to those at cold seeps.

So far, no ANME-related sequences have been published from the deep subsurface (D'Hondt et al., 2004; Newberry et al., 2004; Biddle et al., 2006; Inagaki et al., 2006b; Sorensen and Teske, 2006; Webster et al., 2006). Even in an extensive study by Inagaki et al. sequencing of several thousands of clones obtained from methane hydrate sites from Peru and Cascadia Margin did not result in the retrieval of ANME sequences (Inagaki et al., 2006b). Instead, archaea of the Marine Benthic Group B (MBGB, synonym Deep Sea Archaeal Group, DSAG) and the Miscellaneous Crenarchaeotal Group (MCG) were consistently the dominant phylotypes. Sediments lacking methane hydrates showed no or few MBGB phylotypes. The study by Biddle et al. supported these findings and suggested, based on stable isotopic compositions and intact archaeal lipids that these archaea assimilate organic carbon other than methane (Biddle et al., 2006).

Hydrothermal vents

High methane fluxes are also found at hydrothermal vents of mid ocean ridges (see *Hydrothermal Environments, Marine*), but these ecosystems may not offer many niches for ANME populations. The seafloor of mid ocean ridges consists of basalts and lacks a sediment cover, hence, the habitats for ANME-related organisms are limited to small anoxic zones within vent chimneys (Schrenk et al., 2004; Kelley et al., 2005; Brazelton et al., 2006). Furthermore, the fluids of most hydrothermal vents are sulfate free, and the seawater, which could provide sulfate, is oxygen rich – and hence toxic for ANME organisms. Temperatures range from $<40^\circ\text{C}$ to 90°C at pH 9 to 11. By contrast, sedimentary hydrothermal systems such as the Guaymas basin offer suitable habitats within the surface seafloor similar to the cold seep systems (Teske et al.,

2002; Schouten et al., 2003) although AOM accounts for $<5\%$ of sulfate reduction (Kallmeyer and Boetius, 2004). Another extreme environment in which ANME have been recently found is the CO_2 vented sediments of the Yonaguni Knoll hydrothermal field, southern Okinawa Trough, with an in situ pH <5 (Inagaki et al., 2006a).

Water column

The efflux of methane from cold seeps on the continental margin and mud volcanoes on the abyssal plain make the Black Sea the world's largest surface water reservoir of dissolved methane (Schubert et al., 2006b). Methane concentrations of up to $12 \mu\text{M}$ and AOM rates in the range of nM day^{-1} have been measured (Reeburgh et al., 1991). ANME-1 and ANME-2 archaea are suggested to be responsible for pelagic AOM in the Black Sea (Vetriani et al., 2003; Schubert et al., 2006a, b) accounting each for 3–4% of total cells (Durisch-Kaiser et al., 2005). ANME-1 and ANME-2 appear as single cells in anoxic water, compared to the sediment, where they most often form cell aggregates. Similar to the findings for sediments, one ANME-group dominates, i.e., below approximately 600 m water depth ANME-1 archaea and above 600 m ANME-2 archaea are suggested to be responsible for AOM (Schubert et al., 2006a).

Terrestrial habitats

The presence of ANME has also been reported for terrestrial habitats. ANME-2a archaea are the organisms responsible for AOM activity in a mud volcano field located in the Carpathian Mountains (Romania). Here, thermal alteration of sedimentary organic compounds leads to the release of methane and higher hydrocarbons into the environment (Alain et al., 2006). Additionally, presence of ANME-1 and -2 archaea in a freshwater lake has been reported (Lake Plußsee; northern Germany (Eller et al., 2005)). Long anoxic periods during the summer together with a high organic load in Lake Plußsee favor anaerobic processes in the sediment. In a distinct layer in the anoxic water body, low numbers ($<1\%$) of single ANME archaea were found.

Methane oxidation coupled to denitrification

Methane oxidation could theoretically also be coupled to electron acceptors such as NO_3^- , Fe(III) , and Mn(IV) . Recently, Raghoebarsing et al. (2006) demonstrated AOM coupled to denitrification of nitrate and nitrite in an enrichment culture according to

Anoxic sediment from the Twente canal in the Netherlands was used as inoculum to grow these organisms. The canal contained nitrate concentrations of up to 1 mM and the sediment was saturated with methane, which is typical for freshwater habitats receiving agricultural runoff. The bioreactor biomass was dominated by bacteria of the NC10 clade, a deep branching diverse phylogenetic group (Rappe and Giovannoni, 2003; Raghoebarsing et al., 2006). Recently, the genome of the dominant bacteria *Candidatus Methyloirabilis oxyfera* has been sequenced and surprisingly this apparently anaerobic, denitrifying bacterium encoded, transcribed and expressed the well-established aerobic pathway for methane oxidation, whereas it lacked known genes for dinitrogen production. Isotopic labelling experiments indicated that 'M. oxyfera' bypassed the denitrification intermediate nitrous oxide by the conversion of two nitric oxide molecules to dinitrogen and oxygen, which was used to oxidize methane (Ettwig et al., 2010).

Summary

The AOM is a key biogeochemical process on the Earth, and represents a globally important sink for methane. ANME are present in all environments where methane and sulfate overlap. Unfortunately, no member of the ANME groups or of their sulfate-reducing partner bacteria has been cultivated yet, and the biochemical process is not understood. As long as pure biomass of the archaea is missing, culture-independent molecular tools are the most helpful techniques to investigate the functioning of AOM, including metagenomics and proteomics. Protein patterns of different enrichments help in elucidating the most abundant and hence the most relevant proteins for both partners. Questions to the genome of both partners include for example, whether the ANME themselves may possess the genes for sulfate reduction, and what carbon and energy sources the sulfate reducers could utilize. Answering such questions from metagenomic data sets, however, remains difficult due to the relatively high diversity in the environmental enrichments, and the high proportion of open reading frames in the metagenomes which cannot be assigned to a certain functional category. Here, single cell technologies may provide solutions in the future.

ARCHAEA

Volker Thiel
 University of Göttingen, Göttingen, Germany

Synonyms

Archaeobacteria (term abandoned)

Definition

The Archaea are single-celled or filamentous prokaryotes that constitute the third phylogenetic domain of life, besides the Bacteria and the Eukarya. The word “Archaea” (singular archaeum, archaeon) is derived from the Greek word for “the old ones”.

History

The discovery of the Archaea dates back to 1976 when Carl Woese, at his laboratory at Illinois University, compared prokaryotic small subunit ribosomal RNA sequences using oligonucleotide catalogs (Woese, 2007). Woese recognized *Methanobacterium thermoautotrophicum* as the first member of a fundamentally distinct group of prokaryotes that clustered away from all other bacteria. Consequently, Woese and Fox (1977) established the concept of two separate prokaryotic “urkingdoms,” Eubacteria and Archaeobacteria. Later, the term “Archaeobacteria” was changed to “Archaea” to emphasize the fundamental differences between both groups. Based on these discoveries, Woese and his coworkers proposed the now-accepted division of life into the three domains of Archaea, Bacteria, and Eukarya (Figure 1; Woese et al., 1990).

Specific traits

Like the Bacteria, most Archaea show a cell size between 0.5 and 2 μm and lack a cell nucleus, internal membranes, and organelles. However, a number of traits distinguish the Archaea from members of the other domains of life:

1. The genetic machinery of Archaea is different from Bacteria and Eukarya. The distinctive archaeal “signature” contains more than 1,000 archaeal protein-encoding genes. These signature genes account for a significant portion (9–15%) of archaeal genomic DNA (Graham et al., 2000). The archaeal RNA polymerase, an enzyme producing RNA chains from DNA gene templates, consists of eight (methanogens

Archaea, Figure 1 The phylogenetic tree of life. (Redrawn after Madigan and Martinko, 2006.)

- and halophiles) or ten (hyperthermophiles) individual polypeptides. These polymerases are quite different from those of the Bacteria (four polypeptides), but somewhat similar to those of the Eukarya (10–12 polypeptides; Madigan and Martinko, 2006).
2. Unlike bacteria, the cell walls of the Archaea contain no peptidoglycan (a polymer consisting of sugars and amino acids, also known as murein). Rather, archaeal cell walls exhibit a variety of compositions (Kandler and König, 1998). They may consist of the murein analog pseudomurein, polysaccharides, proteins, or glycoproteins (Madigan and Martinko, 2006).
 3. Archaea possess glycerol-based phospholipids as building blocks of their cell membranes, as do bacteria and eukaryotes. However, some features of the archaeal membrane lipids set them apart, namely (a) the stereochemistry of the glycerol moiety (L instead of R), (b) the linkage between the alkyl chains and the glycerol molecules (ether instead of ester bonds), and (c) the design of the alkyl chains (isoprene-based instead of acyl-based; DeRosa and Gambacorta, 1988). In many archaea, these chains are long enough (C₄₀) to span the whole membrane, forming a monolayer instead of the lipid bilayer typical for other organisms (Koga et al., 1993). These isoprenoid lipids, or degradation products thereof, are excellent tracers for archaea-derived organic matter inputs and biogeochemical processes in modern and ancient sediments (Hopmans et al., 2000; Kuypers et al., 2001; Peckmann and Thiel, 2004; see entry *Biomarkers*).

Phylogeny

Most Archaea, and all cultured species, belong to two major, well-established subdivisions, the Euryarchaeota, which include methanogens and extreme halophiles, and the Crenarchaeota, which encompass predominantly hyperthermophiles and anaerobic respirers (Figure 1). Further lineages, namely Korarchaeota (Barns et al., 1996), Nanoarchaeota (Huber and Rachel, 2007), and the Ancient Archaeal Group (Takai and Horikoshi, 1999), have been proposed based on 16S rDNA amplification from environmental samples and/or co-cultivation in mixed laboratory enrichments (Gribaldo and Brochier-Armanet, 2006; Schleper, 2007). However, most of these newly proposed groups still await detailed characterization.

It is as yet unclear at which time in Earth history the domain Archaea arose (Gribaldo and Brochier-Armanet, 2006). Isotopic signatures indicate the presence of methane-cycling archaea 2.8–2.6 billion years ago. Other molecular estimates placed the divergence between Euryarchaeota and Crenarchaeota even 4.1 billion years ago, but this was inferred by using the plant/animal divergence as a calibration point (Battistuzzi et al., 2004). Unequivocal archaeal biosignatures in Precambrian rocks are therefore urgently needed to provide reliable calibration

points for the molecular dating of Archaea and prokaryotes in general (Gribaldo and Brochier-Armanet, 2006).

Ecology

Until recently, it had been thought that archaea are largely restricted to particular ecological niches. Indeed, many archaea are extremophiles (see entry *Extreme Environments*), with growth optima at the most extreme pH values, ranging from pH 1 (*Sulfolobus acidocaldarius*) to pH 12 (*Natronococcus*). Moreover, numerous species are hyperthermophiles, with growth optima above 80°C. The current record for growth temperatures (122°C) is held by a methanogen, *Methanopyrus kandleri* (Takai et al., 2008). Likewise, many halophilic archaea can tolerate extremely high salt concentrations, even at the saturation limit for NaCl (5.5 M; Barns and Nierzwicki-Bauer, 1997; see entry *Halobacteria – Halophiles*). However, ongoing research employing culture-independent molecular techniques and biomarker studies revealed that archaea are by no means restricted to extreme environments. Rather, they are globally distributed and occur in virtually all “normal” settings as well, including soils and freshwater environments (Schleper, 2007), marine planktonic communities (>20% of the total rRNA, >14% of the total cell counts in sea water; Giovannoni and Rappé, 2000), and marine sediments (Lipp et al., 2008). Archaea are also found as partners in symbioses, e.g., with other archaea (Huber and Rachel, 2007), bacteria (Boetius et al., 2000; Stams and Plugge, 2009), ciliates (van Hoek et al., 2000), sponges (Margot et al., 2002), ruminants (Wright et al., 2006), and even in human intestines (Eckburg et al., 2005; see entry *Symbiosis*).

Metabolism

Some examples for biochemical pathways used by the Archaea are given in Table 1.

The Archaea exhibit a wide range of metabolic capacities, however, all members are chemotrophic. Phototrophy, in a strict sense, does not occur among the Archaea, although some halophilic archaea produce pigments, bacteriorhodopsin-like, light driven proton, or ion pumps that allow them to utilize sunlight for biosynthesis, but in a way very different from phototrophic organisms (Madigan and Martinko, 2006). *Chemoheterotrophic* archaea utilize organic substances, particularly metabolic products of other microbes formed during organic matter degradation (Barns and Nierzwicki-Bauer, 1997). These substrates usually consist of simple C₁ and C₂ compounds, such as methanol or acetic acid. Methane and CO₂ are typical metabolic products of archaeal chemoheterotrophy. *Chemolithotrophic* archaea fix inorganic carbon, with hydrogen gas derived from geochemical processes or microbial metabolism being widely used as an energy source (Pedersen, 1997; Berg et al., 2010).

Some archaea perform iron reduction using Fe(III) as an electron acceptor and hydrogen gas or organic compounds as an electron donor (Bond and Lovley, 2002;

Archaea, Table 1 Some examples for biochemical pathways used by archaea

Reaction	
$2\text{H}_2 + \text{O}_2 \rightarrow 2\text{H}_2\text{O}$	Hydrogen oxidation
$\text{H}_2 + \text{S}^0 \rightarrow \text{H}_2\text{S}$	Sulfur reduction
$4\text{H}_2\text{S} + 2\text{O}_2 \rightarrow 4\text{H}_2\text{SO}_4$	Sulfide oxidation
$2\text{S}^0 + 3\text{O}_2 + 2\text{H}_2\text{O} \rightarrow 2\text{H}_2\text{SO}_4$	Sulfur oxidation
$\text{H}_2 + \text{NO}_3^- \rightarrow \text{NO}_2^- + \text{H}_2\text{O}$	Nitrate reduction
$\text{H}_2 + 2\text{Fe}^{3+} \rightarrow 2\text{Fe}^{2+} + 2\text{H}^+$	Iron reduction
$\text{CO}_2 + 4\text{H}_2 \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$	Methanogenesis (autotrophic)
$4\text{CH}_3\text{OH} \rightarrow 3\text{CH}_4 + \text{CO}_2 + \text{H}_2\text{O}$	Methanogenesis (heterotrophic)
$4\text{CH}_3\text{COO}^- + \text{H}_2\text{O} \rightarrow 3\text{CH}_4 + \text{HCO}_3^-$	Methanogenesis ("acetoclastic," heterotrophic)
Organic compound + $\text{O}_2 \rightarrow 2\text{H}_2\text{O} + \text{CO}_2$	Aerobic respiration

Kashefi et al., 2002; see entry *Fe(III)-Reducing Prokaryotes*). Other members of the Archaea drive pathways of the nitrogen cycle, such as ammonia oxidation, nitrate respiration and denitrification, and assimilatory pathways like N_2 fixation and nitrate assimilation (Cabello et al., 2004; see entry *Nitrogen*). In addition, sulfur is a central component for reactions performed by numerous thermophilic archaea. Elemental sulfur (S^0), thiosulfate ($\text{S}_2\text{O}_3^{2-}$), sulfite (SO_3^-), or sulfate (SO_4^{2-}) may be used as electron acceptors, and elemental sulfur (S^0) or H_2S as electron donors, depending on species and environmental conditions (Barns and Nierzwicki-Bauer, 1997, see entry *Sulfur Cycle*).

Methanogenic archaea (methanogens) are anaerobic euryarchaeotes that produce methane as a metabolic end product of various reactions (Table 1, see entry *Methane, Origin* for details). For several reasons, these archaea are of particularly interest from a geobiological perspective. (a) Chemoorganotrophic methanogens thriving on simple metabolic products of other (micro)organisms such as methanol or acetate (acetoclastic methanogenesis, Table 1) are key players in the degradation of organic matter in sediments (see entry *Carbon (Organic, Degradation)*). (b) Chemolithotrophic methanogens, utilizing only hydrogen gas and CO_2 may thrive in dark and extremely organic-lean environments. (c) Many methanogens are thermophiles (growth temperatures $>60^\circ\text{C}$) or hyperthermophiles (growth temperatures $>80^\circ\text{C}$) with some species being even capable of withstanding temperatures above 100°C (Huber et al., 1990; see entry *Extreme Environments*). Archaea are therefore predestined to pioneering life in extreme settings such as the Deep Biosphere (Hallbeck and Pedersen, 2008), Hot Springs, and Hydrothermal Environments (see these entries). Third, the product of archaeal methanogenesis, "biogenic" methane, may accumulate in sedimentary reservoirs either as free natural gas or, under certain low-temperature/high-pressure conditions, frozen as solid gas hydrates (see entry *Cold Seeps*). Sedimentary methane reservoirs play a crucial role as an energy resource for man, but when released into the atmosphere, methane may act as a strong driving force of global change (Mascarelli, 2009). In as much as methane is an effective

Archaea, Figure 2 Cylindrical cells of archaea belonging to the ANME-1 group of methanotrophic archaea. Individual cells are about $0.5\ \mu\text{m}$ in diameter. (Image courtesy of J. Reitner.)

greenhouse gas being more than 20 times as potent as CO_2 per molecule, it presently contributes more than 20% to the current global greenhouse effect (IPCC, 2007). Several dramatic events in Earth history, such as the Paleocene/Eocene thermal maximum, have been attributed to sudden increases of atmospheric methane concentrations, possibly induced by rapid methane release due to gas hydrate dissolution (Zachos et al., 2008).

Methanotrophic archaea (ANME, *anaerobic methane oxidizers*, Figure 2), organisms that reversed the methanogenic metabolism, have recently been specified as members of sedimentary microbial communities in anoxic sediments. Living together in a syntrophic consortium with sulfate reducing bacteria, ANME oxidize methane by sulfate or nitrate (Raghoebarsing et al., 2006; Knittel and Boetius, 2009; see entry *Anaerobic Oxidation of Methane with Sulfate*).

Biom mineralization

In methane-rich environments, ANME are key players in the formation of calcium carbonate (CaCO_3) deposits, the so-called seep carbonates or methane-derived

Archaea, Figure 3 A Miocene (~16–20 million years old) carbonate deposit that formed as a result of archaeal methanotrophy (Terzi et al., 1994). Croce della Moggiona, Lower Vicchio Formation, Tuscan Apennines, Italy. (Image courtesy of J. Peckmann.)

carbonates (Figure 3; Peckmann and Thiel, 2004; Reitner et al., 2005; see entry *Cold Seeps*). This biologically induced mineralization process is driven by an increase in *Alkalinity* resulting from the anaerobic oxidation of methane. The anaerobic oxidation of methane may also be involved in dolomite ($\text{Ca, Mg}(\text{CO}_3)_2$) precipitation in marine sediments (Moore et al., 2004). Likewise, methanogens have been linked to dolomite formation in shallow groundwater aquifers (Roberts et al., 2004). Recent laboratory experiments identified acetoclastic and autotrophic methanogenesis associated with dolomite formation (Kenward et al., 2009; see entry *Dolomite, Microbial*).

Summary

The Archaea are a group of unicellular prokaryotes representing the third domain of life, in addition to Bacteria and Eukarya. The Archaea differ from the latter by aspects of their genomic machinery, cell wall composition, and membrane lipid structure. Although the timing of their emergence has not been determined, it is believed that the Archaea have been key players within the carbon, nitrogen, and sulfur cycles for the major part of Earth history. Regarding their ecophysiology, individual archaeal groups display unique capacities, such as methanogenesis,

extreme salt tolerance, and survival at temperatures even higher than 100°C. However, environmental surveys revealed the Archaea to be abundant and metabolically versatile not only in extreme environments, but also in “normal” habitats such as soil, oceans, and freshwater. Archaea involved in methane cycling have also been identified as drivers of biologically induced mineralization resulting in (carbonate) rock formation.

Definition

Arsenic, element 33, is a metalloid in row VB of the periodic table. The main oxidation states are arsine (−3) elemental As(0), arsenite (+3), and arsenate (+5). Arsenate, As(V), and arsenite, As(III), are most common, with HAsO_4^{2-} and $\text{H}_2\text{AsO}_4^{1-}$ predominating under oxic conditions and H_3AsO^0 and $\text{H}_2\text{AsO}_3^{2-}$ prevalent in anoxic environments. Arsenic is found in minerals such as arsenosulfides (e.g., arsenopyrite, realgar), iron hydroxides and aluminosilicates (e.g., clays), fossil fuels, geothermal sources, and weathered volcanic and evaporitic deposits. Anthropogenic inputs may also be considerable as organoarsenicals such as roxarsone (3-nitro-4-hydroxy benzene arsonic acid) and monosodium and disodium methyl arsonate continue to see wide spread use. The toxicology of arsenic is well known; As(V) is an analog of phosphate and can disrupt oxidative phosphorylation, while As(III) binds to sulfhydryl groups and can inhibit respiratory enzymes. Nevertheless, arsenic is readily metabolized by microorganisms, undergoing redox reactions involved in resistance or energy generation. Organarsenicals are used for energy generation or as a carbon source. Environments with elevated concentrations can support a diverse arsenic metabolizing microbial community and a robust biogeochemical cycle (Oremland and Stolz, 2003).

As(III)-oxidizing prokaryotes are found among the alpha-, beta-, and gamma-proteobacteria, Deinocci (i.e., *Thermus*), and Crenarchaeota. Physiologically diverse, they include heterotrophic and chemolithoautotrophic species. The oxidation of arsenite involves the arsenite oxidase (AoxAB or AroBA), a member of the molybdenum family of enzymes. The gene sequence of the catalytic subunit (*aoxB* or *aroA*) is highly conserved, and oligonucleotide primers have been used to investigate the occurrence and distribution of As(III)-oxidizing

species. The dissimilatory reduction of As(V) has been demonstrated in Crenarchaeota, thermophilic bacteria, gamma-, delta-, and epsilon-proteobacteria, and low and high mole %GC gram positive bacteria. The enzyme, ArrAB, is also a molybdoenzyme, but differs significantly from AoxBA. The *arrA* gene has also been used as an environmental probe. Arsenic resistance involves a completely different type of arsenate reductase (ArsC, ACR2). Three different but comparable resistance systems (e.g., *E. coli*, *Staphylococcus*, *Saccharomyces*) have been described. ArsC catalyzes the reduction of arsenate to arsenite, while an arsenite-specific efflux pump (ArsB, ACR3) expels As(III) from the cell. Additional components include an ATPase (ArsA) and regulatory elements (ArsR, ArsD). Far less is known about arsenic methylation and demethylation, however, a SAM-dependent methylase has recently been described (Stolz et al., 2006).

Different microbially mediated processes can result in arsenic contaminated aquifers including (1) the oxidation of arsenic-containing pyrites, (2) the release of As(V) from reduction of iron oxides by autochthonous organic matter, (3) the reduction of iron oxides by allochthonous organic matter from dissolved organics in recharging waters, (4) the exchange of adsorbed As(V) with fertilizer phosphates, and (5) recharge with water contaminated with inorganic arsenic derived from the application or production of wood preservatives, pesticides (e.g., calcium arsenate), and organoarsenicals (e.g., roxarsone). Thus organisms that metabolize arsenic can impact the speciation, mobility, and toxicity of arsenic in the environment (Oremland and Stolz, 2005).

species. The dissimilatory reduction of As(V) has been demonstrated in Crenarchaeota, thermophilic bacteria, gamma-, delta-, and epsilon-proteobacteria, and low and high mole %GC gram positive bacteria. The enzyme, ArrAB, is also a molybdoenzyme, but differs significantly from AoxBA. The *arrA* gene has also been used as an environmental probe. Arsenic resistance involves a completely different type of arsenate reductase (ArsC, ACR2). Three different but comparable resistance systems (e.g., *E. coli*, *Staphylococcus*, *Saccharomyces*) have been described. ArsC catalyzes the reduction of arsenate to arsenite, while an arsenite-specific efflux pump (ArsB, ACR3) expels As(III) from the cell. Additional components include an ATPase (ArsA) and regulatory elements (ArsR, ArsD). Far less is known about arsenic methylation and demethylation, however, a SAM-dependent methylase has recently been described (Stolz et al., 2006).

Different microbially mediated processes can result in arsenic contaminated aquifers including (1) the oxidation of arsenic-containing pyrites, (2) the release of As(V) from reduction of iron oxides by autochthonous organic matter, (3) the reduction of iron oxides by allochthonous organic matter from dissolved organics in recharging waters, (4) the exchange of adsorbed As(V) with fertilizer phosphates, and (5) recharge with water contaminated with inorganic arsenic derived from the application or production of wood preservatives, pesticides (e.g., calcium arsenate), and organoarsenicals (e.g., roxarsone). Thus organisms that metabolize arsenic can impact the speciation, mobility, and toxicity of arsenic in the environment (Oremland and Stolz, 2005).

Synonyms

Homoacetogens

Definition

Acetogens are defined as anaerobic prokaryotes that use the acetyl-CoA pathway for the (a) reductive synthesis of the acetyl moiety of acetyl-CoA from CO₂, (b) conservation of energy, and (c) assimilation of CO₂ into biomass.

Introduction

Acetogens utilize the acetyl-CoA “Wood–Ljungdahl” pathway as a terminal electron-accepting, energy-conserving, CO₂-fixing process. The reductive synthesis of acetate from CO₂ differentiates acetogens from organisms that synthesize acetate by other metabolic processes. Although the production of acetate as a sole reduced end product is the classic hallmark of acetogens, the production of acetate is not a part of the definition, because the acetogen might not form acetate in situ or when cultured in the laboratory.

The first acetogen, *Clostridium aceticum*, was isolated from soil by the Dutch microbiologist K. T. Wieringa in 1936. This spore-forming, mesophilic bacterium was shown to grow at the expense of H₂–CO₂ and synthesizes acetate according to the following stoichiometry (Wieringa, 1939–1940):

In 1936, this reaction constituted a unique mechanism for the fixation of CO₂. Unfortunately, the culture of

C. aceticum was lost and no further work was done until it was re-isolated in the early 1980s (Braun et al., 1981). In 1942, F. E. Fontaine and coworkers isolated the second acetogen, *Clostridium thermoaceticum* (later reclassified as *Moorella thermoacetica*), a spore-forming, thermophilic bacterium that catalyzed the near stoichiometric conversion of glucose to acetate (Fontaine et al., 1942):

C. thermoaceticum became the most extensively studied acetogen and was used to resolve the enzymology of the acetyl-CoA pathway in the laboratories of two biochemists, H. G. Wood and L. G. Ljungdahl (Drake and Daniel, 2004).

The demonstration that ¹⁴CO₂ was incorporated equally into both carbons of acetate by *C. thermoaceticum* was the first ¹⁴C-study in biology (Barker and Kamen, 1945). The synthesis of acetate from two molecules of CO₂ was later confirmed by Wood using ¹³CO₂ and mass spectrometry (Wood, 1952). Both studies demonstrated that acetogens featured a new autotrophic mechanism for the fixation of CO₂. The acetyl-CoA pathway, also referred to as the Wood–Ljungdahl pathway, is now recognized as a fundamental component of the global carbon cycle, important to primary production in subsurface-ecosystems, and essential to the metabolic potentials of not only acetogens but also methanogens, sulfate-reducers, and anammox bacteria (Wood and Ljungdahl, 1991; Drake, 1994; Schouten et al., 2004).

The acetyl-CoA Wood–Ljungdahl pathway

The acetyl-CoA pathway is a reductive, linear, “one-carbon” process (Figure 1) in contrast to cyclic CO₂-fixing processes (Calvin cycle, reductive tricarboxylic acid cycle, and hydroxypropionate cycle). The two branches of the acetyl-CoA pathway merge at the synthesis of acetyl-CoA that is converted to either acetate or

Acetogens, Figure 1 The acetyl-CoA “Wood-Ljungdahl” pathway. H_4F , tetrahydrofolate; HSCoA , coenzyme A; P_i , inorganic phosphate; e^- , electron; co-protein, corrinoid enzyme; ATP, adenosine-5'-triphosphate. The pathway is from Müller et al. (2004) and used with kind permission of Horizon Bioscience.

assimilated into biomass (Drake, 1994; Drake et al., 2006). Acetyl-CoA synthase (ACS) not only catalyzes the reduction of CO_2 to CO and the synthesis of acetyl-CoA but also oxidizes CO to CO_2 . Thus, the acetyl-CoA synthase is also termed CO dehydrogenase (CODH). Energy conservation occurs during the reductive synthesis of acetate by substrate-level phosphorylation and chemiosmotic processes. For each glucose that is converted to three acetates, four molecules of ATP are produced by substrate-level phosphorylation (ATP_{SLP}). However, when growth occurs under autotrophic conditions, there is no net gain in ATP_{SLP} and growth is dependent upon translocation of protons or sodium ions.

The relatively simple features of the linear acetyl-CoA pathway and the fact that metals and metal sulfides do the biochemical work of CO_2 fixation in the key enzymes of the pathway (i.e., CODH and ACS) suggest that the acetyl-CoA pathway might have been the first autotrophic and early respiratory process on earth and, thus, important in the evolution of life (Wood, 1991; Miyakawa et al.,

2002; Russel and Martin, 2004). It has been proposed that biochemistry started when marine CO_2 from volcanoes and hydrothermal H_2 met at a hydrothermal vent rich in metal sulfides, where an analogue of the exergonic acetyl-CoA pathway catalyzed the synthesis of organic precursors to fuel primordial biochemical reactions.

Phylogenetic diversity of acetogens

Over 100 acetogenic bacterial species have been isolated to date from very diverse habitats, including marine and freshwater sediments; salt lake soda deposits; tundra, forest, and agricultural soils; the subsurface; fecal material; and marine and salt marsh plants (Drake et al., 2006, 2008). Acetogens display extreme genetic diversity, having genomic G + C contents that vary between 22 mol% (*Clostridium ljungdahli*) to 62 mol% (*Holophaga foetida*). Acetogens have been assigned to 22 different bacterial genera including *Acetivibrio*, *Acetobacterium*, *Acetohalobium*, *Acetonebium*, *Bryantella*, “*Butyrivibrio*,” *Caloramator*, *Clostridium*, *Eubacterium*, *Holophaga*, *Moorella*, *Natroninella*, *Natronincola*, *Oxobacter*, *Ruminococcus*, *Sporomusa*, *Syntrophococcus*, *Tindallia*, *Thermoacetogenium*, *Thermoanaerobacter*, and *Treponema* (the name in quotation marks has not been validated). The diverse habitat range of acetogens demonstrates that they are adapted to a broad range of in situ conditions. Many acetogens are sporeformers (e.g., Byrner et al., 2000), a feature that aids in surviving unfavorable in situ conditions, and some acetogens have connecting filaments (Küsel et al., 2001) that might facilitate communication. The usage of the acetyl-CoA pathway for autotrophic assimilation of carbon and acetate utilization by methanogens suggests that Archaea also can grow via acetogenesis. Indeed, the methanogen *Methanosarcina acetivorans* C2A uses the acetyl-CoA pathway to convert carbon monoxide to both acetate and methane, that is, methane is not the sole reduced end product of this methanogen (Rother and Metcalf, 2004; Lessner et al., 2006). Similarly, the archaea *Archaeoglobus fulgidus* VC16 can grow via CO -dependent acetogenesis (Henstra et al., 2008).

Only some acetogenic genera, like *Moorella* and *Sporomusa*, are monophyletic, but many acetogens are phylogenetically dispersed within genera that contain non-acetogenic species. Thus, the phylogenetic position of 16S rRNA gene sequences is usually inadequate for resolving the functional identity of a potential acetogen. To date, only some highly specific 16S rRNA-based probes and primers have been designed to target subsets of acetogenic taxa (Küsel et al., 1999). Molecular approaches based on the analysis of functional genes central to the acetyl-CoA pathway (e.g., a gene for formyltetrahydrofolate synthetase) are still limited due to problems of probe specificity (Leapheart et al., 2003).

Functional diversity of acetogens

Acetogens utilize a wide variety of electron donors and electron acceptors and can engage alternative terminal

electron-accepting processes when challenged with O_2 (Drake et al., 2006). Many acetogens can utilize one or more terminal electron-accepting processes in addition to acetogenesis. For example, nitrate is a preferred electron acceptor for *M. thermoacetica* and is dissimilated to nitrite and ammonium (Seifritz et al., 1993), and perchlorate is a preferred terminal electron acceptor for *Moorella perchloratireducens* (Balk et al., 2008). The engagement of diverse redox couples enables acetogens to form junction points within and between biological cycles at the ecosystem level (Drake and Küsel, 2005). Acetogens are known to use the following alternative terminal electron acceptors that yield diverse end products listed below:

Fumarate → succinate
 Methoxylated phenylacrylates → methoxylated phenyl propionates
 Nitrate → nitrite
 Nitrite → ammonium
 Thiosulfate → sulfide
 Dimethylsulfoxide → dimethylsulfide
 Perchlorate → chloride
 Chlorate → chloride
 Pyruvate → lactate
 Acetaldehyde → ethanol
 Protons → hydrogen gas

CO , H_2 , carbohydrates, alcohols, carboxylic acids, dicarboxylic acids, aldehydes, substituent groups of various aromatic compounds, and certain halogenated substrates are examples of substrates that acetogens can oxidize. Although hexoses or pentoses are utilized by most of the acetogens isolated to date, none of these isolates appear to be able to degrade high molecular weight polymers, such as cellulose and lignin. Most acetogens have the capacity to produce more than acetate as their sole reduced end product, and this capacity is dependent on the availability of both reductant and terminal electron acceptors, including CO_2 . Thus, referring to acetogens as homoacetogens is usually a misnomer.

In anoxic habitats, acetogens compete with primary fermentors for monomeric compounds that are derived from the initial breakdown of cellulose and lignin and with secondary fermentors for fermentation products. Thermodynamic considerations suggest that acetogenesis should not be a highly competitive microbial process. Nonetheless, acetogens can outcompete methanogens for H_2 in freshwater sediments with low pH and low temperature and in the hindgut of certain termites (Conrad et al., 1989; Breznak and Kane, 1990; Drake et al., 2006). Microbially produced acetate can provide up to 100% of the energy requirement of wood-feeding termites. The attachment of H_2 -consuming acetogenic spirochetes to H_2 -producing protozoa provides H_2 concentrations above the known H_2 -threshold values for acetogens.

Another ecological advantage might be the low oxygen sensitivity of certain acetogens (Figure 2). Acetogens have been classically referred to as obligate, if not strict, anaerobes, and many enzymes central to acetogenesis are

Acetogens, Figure 2 Mechanisms by which acetogens cope with oxidative stress. X, products (e.g., H_2 , formate, lactate) that are derived from the partial oxidation of carbohydrates (in some cases, short-chain polymers [e.g., stachyose] that are not substrates for the acetogen); e^- , electron. (Modified from Müller et al., 2004, and used with kind permission from Horizon Bioscience.)

extremely sensitive to O_2 . However, acetogens have been isolated from oxic habitats, like soils and the rhizosphere of macrophytes that release O_2 through their roots, indicating that such acetogenic species must cope with periods of oxidative stress. Acetogens contain numerous enzymes that can reductively remove O_2 and its toxic by-products (e.g., superoxide and peroxide), when the concentration of O_2 is relatively low (Drake et al., 2006). These enzymes include peroxidase, NADH-oxidase, rubredoxin oxidoreductase (a superoxide reductase), rubrerythrin (a peroxidase), superoxide dismutase, catalase, and cytochrome *bd* oxidase (Das et al., 2001, 2005; Küsel et al., 2001). Acetogens can shift the flow of reductant away from the acetyl-CoA pathway to alternative terminal electron-accepting processes that are less sensitive to O_2 and operate at higher redox potentials than the very low standard redox potential of the CO_2 /acetate half-cell reaction (-290 mV). For example, *Clostridium glycolicum* RD-1 (isolated from seagrass roots) is an aerotolerant acetogen that switches from acetogenesis to

classic fermentation in response to O₂ (Küsel et al., 2001). Acetogens can also form symbiotic relationships with O₂-consuming microaerophiles and aerotolerant fermenters (Göbner et al., 1999). The microaerophile can be a fermentative non-acetogen that has the capacity to consume O₂ and forms fermentation products (e.g., lactate, formate, and H₂) that can be used by the acetogen for acetogenesis. Such interactions can protect acetogens from oxidative stress and form trophic linkages in habitats with fluctuating redox conditions.

Conclusions

It has been estimated that approximately 10¹² kg of acetate is synthesized per year via H₂-driven acetogenesis in sediments and the hindgut of termites (Breznak and Kane, 1990), a number that is fivefold greater than the annual amount of methane produced via the methanogenic reduction of CO₂. Such estimates accentuate the potential importance of acetogens and acetogenesis to the global carbon cycle. However, in situ acetate turnover measurements are complicated and acetogens catalyze a large number of redox reactions, suggesting that their in situ activities are not restricted to acetogenesis. Thus, although acetate forms an important trophic link in a wide variety of ecosystems, in situ information on acetogens and their activities are often theoretical.

ACID ROCK DRAINAGE

Lesley A. Warren
 McMaster University, Hamilton, ON, Canada

Synonyms

Acid mine drainage; AMD; ARD

Definition

Acid mine and acid rock drainage (AMD/ARD) refer to the extremely acidic ($pH < 3$), metal-rich waters that are derived from the weathering of sulfidic minerals when exposed to air, water, and microorganisms ([Figure 1](#); Nordstrom and Alpers, [1999](#); Bond et al., [2000](#)):

Acid Rock Drainage, Figure 1 An AMD stream at a nickel-copper mine in northern Ontario, Canada. The orange and red colours in the stream are Fe-oxyhydroxide and Fe-sulphate mineral precipitates.

Environmental significance

AMD/ARD is considered to be the most important and widespread global-mining-industry-related pollution problem (Rowe et al., [2007](#)). The main characteristics of ARD/AMD are (1) low pH, (2) high concentrations of dissolved heavy metals, and (3) high concentrations of sulfate (SO_4^{2-} , Tsukanoto et al., [2004](#)). Total dissolved metal concentrations as high as 200,000 mg/L and dissolved SO_4^{2-} as high as 760,000 mg/L have been reported to be associated with AMD (Nordstrom et al., [2000](#)).

AMD/ARD generation

AMD is generated through a combination of chemical and biological (microorganism) processes by which sulfidic minerals are converted to sulfates and iron oxyhydroxides

when exposed to water and oxygen (see [Sulfide Mineral Oxidation](#)). The overall oxidative dissolution of pyrite (FeS_2), a widespread common mine constituent, and associated with AMD generation is given by [Equation 1](#):

This process progressively increases water acidity, resulting in the mobilization of metals from mine wastes. AMD generation is typically amplified when the reactions involved in the overall process, described in [Equation 1](#), are catalyzed by aerobic Fe- and S-oxidizing bacteria, such as *Acidithiobacilli* (formerly *Thiobacilli*, e.g., *Acidithiobacillus ferrooxidans*; see [Biomining \(Mineral Bioleaching, Mineral Biooxidation\)](#); [Sulfide Mineral Oxidation](#)). However, factors such as levels of microorganism activity, pH, sulfide mineral area, crystallography, type of sulfide mineral, temperature, and oxygen concentration all interactively influence the rate of AMD generation (Berghorn and Hunzeker, 2001).

[Figure 2](#) provides a schematic illustrating the overall AMD generation process. Initiation at neutral pH occurs through the release of ferrous iron (Fe^{2+}) and acid (H^+) into solution ([Equation 2](#)):

At pH values <4 , increased solubility of ferric iron promotes Fe^{3+} pyrite oxidation ([Equation 3](#)) at far greater rates than those associated with O_2 oxidation:

At pH values greater than 4, O_2 -driven oxidation of ferrous iron to ferric iron ([Equation 4](#)) results in Fe oxyhydroxide formation ([Equation 5](#)) and iron removal through precipitation:

In addition, as the pH decreases below 4, iron-oxidizing bacteria, many of which are adapted to pH values of 2–4, substantively increase rates of Fe oxidation ([Equation 4](#)) by factors greater than 10^6 . For these reasons, the oxidation of Fe^{2+} to Fe^{3+} is often referred to as the rate-determining step in the acid generation process. Thus, once the system reaches pH values less than 4, a self-perpetuating cycle of Fe^{3+} -driven oxidation of pyrite and regeneration of Fe^{3+} through Fe oxidizers is initiated, producing more acidity and Fe^{2+} until either ferric iron or the pyrite waste is depleted ([Figure 2](#)).

Acid Rock Drainage, Figure 2 A schematic of AMD generation based on FeS_2 , indicating the relative importance of O_2 vs Fe^{3+} -driven oxidation rates and the role of microorganisms as a function of pH. At low pH, Fe^{3+} -driven pyrite oxidation releases greater acidity than O_2 -driven pyrite oxidation, which is more favourable at circumneutral pH values.

Treatment of acid mine drainage

AMD waters must be treated to remove metals and raise the pH before they are discharged to a receiving environment (Neculita et al., 2007). Numerous approaches, often characterized as active or passive, exist to treat AMD. Active processes refer to operations that require a relatively high degree of management and continuous input of consumables, while passive processes theoretically require minimal management and other costs once they are established (Johnson, 2006). The most widespread method is active treatment involving the addition of a chemical neutralizing agent or base (i.e., lime or Ca oxide, CaCO_3 , Na/Mg carbonates, Na/Mg hydroxides) to increase water pH and precipitate metals as hydroxides and carbonates. Over the last 20 years, there have been considerable new developments for AMD treatment including constructed wetlands (Johnson and Hallberg, 2002), bioreactors, and permeable reactive barriers (Blowes et al., 2000), which take advantage of the increasing knowledge of microbially driven reactions. Much of the biotechnology developments rely on sulfate-reducing bacteria (SRB) to treat AMD. Fundamentally, bioreactors use SRB to drive sulfide precipitation, removing metals from the AMD solution (Equations 6 and 7):

where M^{Z+} is a cationic metal such as Cu or Ni.

In addition, SRB will drive alkalinity generation (Equation 6) (Koschorreck and Tittel, 2007). However, all emerging treatment approaches are challenged with regard to long-term efficiency. In large part, this reflects the challenges in identifying the complex and dynamic reactions involved in the overall AMD process. The exact mechanisms and controls involved in reactions as well as an understanding and identification of the microbial flora required to efficiently drive desired reactions for bioreactors over the long-term have not yet been elucidated (Edwards et al., 2000; Bernier and Warren, 2005; Bernier and Warren, 2007). In particular, growing evidence of the importance of consortia or mixed microorganism communities in driving AMD-associated processes underscores the need to more fully investigate the interactive roles of bacteria, system pH, $[\text{Fe}]$, $[\text{O}_2]$, and other [metals] involved in the process to narrow the gap in determining effective long-term strategies to mitigate AMD.

Summary

AMD/ARD refer to metal-rich acidic waters that are generated through the exposure of sulfidic minerals in mine wastes to water, oxygen, and microorganisms. These discharges are a significant global pollution issue associated with mining activities. Both sulfur- and iron-oxidizing bacteria are involved with Fe-oxidizing bacteria playing a key role in the increased rates of AMD generation compared to abiotic (nonbiologically stimulated oxidation) sulfidic wastes. AMD must be treated for the high levels of acidity and metals before it can be released to the

environment. New treatment strategies are emerging that include some combination of chemical and biological approaches; however, all are challenged with regard to long-term efficacy. New research evaluating the roles of environmentally mixed communities of microorganisms demonstrates the opportunities to harness environmentally occurring microorganisms to combat AMD.

ACIDOPHILES

“Acidophiles” are organisms thriving in environments below pH 5. For details, see entries “*Extreme Environments*,” “*Biomining (Mineral Bioleaching, Mineral Biooxidation)*,” “*Hot Springs and Geysers*,” *Hydrothermal Environments (Marine)* and “*Acid Rock Drainage*.”

ACRITARCHS

Acritarchs are organic-walled acid-resistant microfossils known from the Proterozoic and throughout the Phanerozoic. The position of these microfossils is still uncertain. A number of acritarch genera have been assigned to Green Algae; others are considered to bear some resemblance to the cysts of dinoflagellates. For more information, please refer to entries “Algae, Eukaryotic” and “Protozoa.”

AEROBIC METABOLISM

Heribert Cypionka
University of Oldenburg, Oldenburg, Germany

Synonyms

Aerobic respiration; Oxygen metabolism

Definition

Aerobic metabolism comprises the reduction of molecular oxygen as electron acceptor of aerobic respiration, its use as cosubstrate in the degradation of certain compounds, and reactions leading to the detoxification of partially reduced oxygen species.

Introduction

Life has evolved in the absence of molecular oxygen (see Chapter *Early Earth*). Therefore, it is not surprising that basic metabolic pathways involved in growth and cell division (like DNA replication or protein synthesis) do not depend on the presence of molecular O₂. The evolution of the oxygen-producing (oxygenic) phototrophs dramatically changed the situation of living organisms. Molecular oxygen raised the redox potential of the environment and enabled microorganisms to respire with a much higher energy yield than before. Although oxygen is involved in

a limited number of reactions only, its presence or absence has fundamental impact on biogeochemical processes.

Aerobic degradation of organic matter

Aerobic respiration consumes a major part of the photosynthetically produced O₂ and about 90% of the organic matter (see Chapter *Carbon Cycle*). Aerobic (oxygen-metabolizing) organisms normally oxidize their substrates completely to CO₂. In most cases, O₂ is not directly involved in this process. Substrate oxidation generates reduced electron carriers by means of the respiratory chain. Oxygen is reduced as the last step of the respiration process.

Respiratory chain

Respiration is a membrane-bound process that generates a chemiosmotic proton gradient across the membrane (Mitchell, 1966). Respiratory chains are composed of series of enzymes, which are organized in multienzyme complexes and use cofactors that allow the stepwise transport of reducing equivalents to oxygen (Figure 1). In eukaryotes (plants, animals, fungi) it takes place within the mitochondria, which are assumed to have evolved from endosymbiotic bacteria. In prokaryotes (Bacteria, Archaea), the respiratory chain is located in the cytoplasmic membrane. The respiratory chain of the bacterium *Paracoccus denitrificans* appears to have many similarities to the mitochondrial type (Harold, 1986). However, many bacteria have variations compared to the mitochondrial type presented in Figure 1.

Energetics and ATP conservation

Most reducing equivalents are fed into the respiration process via NADH₂, which has a standard redox potential (E_0') of -0.32 V. The terminal electron-accepting redox pair O₂/H₂O has redox potential of $+0.82$ V. Thus, the usable redox potential is about 1.14 V. From this redox potential one can calculate a standard $\Delta G_0'$ of -440 kJ per mol of O₂. Assuming that ATP conservation requires about -75 kJ per mol, the conservation of 5 to 6 ATP per O₂ reduced is possible. As a consequence of the high ATP yield, aerobic organisms can form more biomass from the same amount of substrate than anaerobic organisms.

Use of oxygen as cosubstrate

Molecular oxygen is used as a cosubstrate in some catabolic and anabolic reactions (Lengeler et al., 1999). The enzymes involved are called mono- or di-oxygenases, depending on the number of oxygen atoms transferred to their substrate. Oxygenases are used by aerobes to activate certain substrates that do not have functional groups that allow a simple degradation. They catalyze the initial hydroxylation of hydrocarbons to yield alcohols that can easily be metabolized further. They are also involved in the ring cleavage of aromatic compounds and in the first oxidation step of ammonia oxydation. Anaerobic organisms are either unable to oxidize the substrates activated

Aerobic Metabolism, Figure 1 Principle of respiratory electron transport and vectorial proton translocation. The first proton translocating complex (with FMN and FeS as prosthetic groups) channels electrons to the quinones (UQ), which perform a cycle, again coupled to proton translocation. Electrons move on to the cytochrome bc_1 -complex, via cytochrome c to the copper-containing terminal cytochrome oxidase (Cyt aa_3). O_2 is reduced in the last step only. The ATP synthesis coupled to reentry of the translocated protons is independent of the electron transport process. (From Cypionka, 2006.)

by means of oxygenases or possess different degradation pathways.

Anabolic reactions making use of molecular oxygen are the biosynthesis pathways of tetrapyrroles, ubiquinones, pyrimidines, sterols, and unsaturated fatty acids. Again,

either the products are absent in strict anaerobes (e.g., sterols), or anaerobes have found alternative pathways for their biosynthesis.

Toxic forms of oxygen and detoxification

Aerobic metabolism inevitably generates small amounts of partially reduced toxic oxygen species (Lengeler et al., 1999). These are the superoxide anion ($O_2^{\cdot-}$), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($\cdot OH$). These species can be formed via nonenzymatic one-electron reduction steps (e.g., with Fe^{2+} , quinols, or H_2S) or by nonspecific reactions with reduced flavoproteins. Aerobic bacteria can remove toxic oxygen species by nonenzymatic reactions (e.g., with glutathione) or by means of enzymes: Superoxide dismutase (SOD) converts superoxide to H_2O_2 , and catalyze dismutates H_2O_2 to water and O_2 . These enzymes often lack in strict anaerobes, which might explain their sensitivity toward oxygen.

Distribution of the aerobic lifestyle

Many microorganisms can thrive in oxic (oxygen-containing) as well as in anoxic (free of oxygen) environments. Those are classified as facultative aerobes (or facultative anaerobes). This means that they can rely on aerobic respiration as well as on respiration with other electron acceptors or on fermentative energy conservation. Groups of strict anaerobes comprise methanogens, sulfate reducers, and Clostridia. Even in strict anoxic (oxygen-free) environments facultative aerobes can be found (Süß et al., 2006).

Summary

Aerobic respiration is the most effective way of energy conservation. It is used to oxidize the major part of the organic matter on Earth. During aerobic respiration oxygen is reduced to water. In some cases, O_2 is used by oxygenases for the hydroxylation of inert substrates. Aerobic organisms have enzymatic and nonenzymatic mechanisms to detoxify partially reduced oxygen species such as superoxide or hydrogen peroxide.

ALGAE (EUKARYOTIC)

Thomas Friedl¹, Nicole Brinkmann¹, Kathrin I. Mohr^{1,2}

¹University of Göttingen, Göttingen, Germany

²Helmholtz Centre for Infection Research, Braunschweig, Germany

Algae (eukaryotic)

Eukaryotic algae are a collection of extremely diverse, nonrelated organisms that perform photosynthesis in plastids, permanent organelles of green, brown, or bluish colors derived from endosymbiosis. In contrast to plants, algae do not form embryos.

Algae is a term of convenience and refers to a collection of highly diverse organisms that undertake photosynthesis and/or possess plastids (Keeling, 2004). Many authors even include the prokaryotic cyanobacteria into the algae, because they exhibit a life-style rather similar to their eukaryotic counterparts and often share the same habitat with eukaryotic algae. Cyanobacteria form the origin of plastids (for reviews see McFadden, 2001; Keeling, 2004; Palmer, 2003). Plastids are the organelles of plants and eukaryotic algae that harbor photosynthesis and synthesize many chemical compounds also important for other biochemical pathways (e.g., aromatic amino acids, heme, isoprenoids, and fatty acids); nonphotosynthetic plastids are known from plants and many algal groups (Williams and Keeling, 2003). Recently, from strategies of synthesizing various information, that is, mainly DNA sequence analyses of concatenated genes as well as the incorporation of discrete characters such as insertions, deletions, and gene fusion events, and consideration of morphology and biochemistry, a phylogeny of eukaryotes has emerged which consists of five “supergroups” (Keeling, 2004). Algae are scattered among four of the five major eukaryotic groups. The “Plantae” comprises exclusively eukaryotes with plastids derived from primary endosymbiosis, that is, they are bound by two membranes, derived from the inner and outer membranes of a cyanobacterium which was transformed into an organelle through uptake and retention by the host cell followed by the loss of much of its genome (Keeling, 2004). The Plantae are formed by three distinct but related lineages, the viridiplantae (which comprises all green algae and land plants or embryophytes), the rhodophytes (red algae), and the glaucophytes. The “Chromalveolates” comprises large and abundant algal groups such as the heterokont algae (e.g., diatoms and brown algae), the haptophytes,

the alveolates (which include the dinoflagellates and apicomplexans), and the cryptomonads. Only a single lineage of each of the “Excavates” and “Rhizaria” includes algae, the euglenoids and chlorarachniophytes. Except for the Plantae, all other eukaryotic algal lineages acquired their plastids through secondary endosymbiosis (for reviews see McFadden, 2001; Keeling, 2004; Palmer, 2003). Secondary plastids are surrounded by four or three membranes which resulted from phagocytosis of a primary alga, which was either a red alga or a green alga. In secondary plastids of both red and green origin, the primary algal nucleus is highly reduced (in the cryptomonads and chlorarachniophytes) or more commonly lost altogether (e.g., in the heterokonts and haptophytes; Keeling, 2004).

Green algae (Plantae supergroup)

The green algae are photosynthetic eukaryotes with double membrane-bound plastids (derived from primary endosymbiosis), stacked thylakoids, and the chlorophylls *a* and *b*. Their other accessory pigments are the carotenoids, beta-carotene, and xanthophylls. The main reserve polysaccharide is starch which is deposited inside the plastid (Lewis and McCourt, 2004; Pröschold and Leliaert, 2007). A few genera (e.g., *Prototheca*) contain non-photosynthetic plastids which lost their pigments secondarily. Apart from plastid-associated features, a unique stellate structure linking nine pairs of microtubules in the flagellar base of those green algae that are motile or produce motile stages is characteristic, as well as cell walls composed of cellulose which is present in most green algae (Graham et al., 2009). Most of these characters are shared with embryophytes (land plants) and, therefore, the green algae are difficult to define to the exclusion of the latter. The green algae have evolved in two major lineages (Friedl, 1997; Karol et al., 2001; Lewis and McCourt, 2004). One lineage, the chlorophyte lineage (Chlorophyta *sensu* Bremer, 1985; Sluiman, 1985) comprises the majority of green algal diversity (i.e., the green algae in a more narrow sense or the majority of what have been traditionally called green algae) with a bewildering array of morphologies attributable to at least five different morphological organizations (Pröschold and Leliaert, 2007). Examples of microscopic green algae reported from freshwaters with high calcification levels are rather small coccoid forms (e.g., *Chlorella*-like, Figure 1a; *Desmochloris*, Figure 1d; *Pseudendocloniopsis*, Figure 1f), coccoids that form coenobia (e.g., *Scenedesmus*, Figure 1b) or are of filamentous organization which may easily disintegrate into unicells (e.g., *Stichococcus*, Figure 1c) or form small thalli of branched filaments (e.g., *Pseudendoclonium*, Figure 1e). Also some monadoid (flagellated unicells) green algae and the siphonocladous *Cladophora* are well known from highly calcifying freshwater habitats. Several marine green algae of coenocytic organization precipitate carbonate and belong to the

Algae (Eukaryotic), Figure 1 Eukaryotic algae recovered from tufa stromatolite biofilms of hardwater creeks: (a) *Chlorella*-like coccoid green alga (Trebouxiophyceae, pure culture), (b) coenobia of coccoid green alga *Scenedesmus* sp. (Xanthophyceae, pure culture), scale bar 20 μm .

calcareous algae, for example, the orders Dasycladales (Kingsley et al., 2003) and Caulerpales (Stanley et al., 2010). Whether the aforementioned freshwater green algal taxa are involved in carbonate precipitation is still

unknown, but microscopic freshwater green algal genera with calcite deposits on their surfaces are several members of Zygnematales (e.g., *Oocardium*) and *Gongrosira* (Rott et al., 2009; Freytet and Verrecchia, 1998). The other major

green algal lineage, the charophyte clade (*sensu* Lewis and McCourt, 2004), contains a smaller number of widespread, mostly freshwater green algae. Examples from the charophyte clade which are associated with calcification are the orders Zygnematales and Charales, for examples, the genus *Chara* is known for its extracellular carbonate production (McConnaughey, 1991). The charophyte green algae represent the closer relatives of land plants (embryophytes) with the Charales being most closely related to embryophytes (Karol et al., 2001; Lewis and McCourt, 2004). In the three lineages of green algae where calcite accumulation is known, that is, the orders Caulerpales, Dasycladales and Zygnematales (Bilan and Usov, 2001), aragonite deposits are outside of the cell wall but inside a specialized sheath. The crystal bundles are organized in layers, which are parallel to the filaments of this porous multilayer sheath and have also calcium oxalate inclusions. The chemical composition of the sheath and its role in the calcification process are unknown for the majority of species. It may simply be a barrier preventing the diffusion into the surrounding medium, although its direct participation in the initiation of the crystal formation cannot be excluded (Bilan and Usov, 2001). A third group of green algal taxa, called prasinophytes, consists of “primitive”-appearing unicells of uncertain affinity. Most known prasinophyte green algae form several early diverging clades within the phylogeny of the Chlorophyta (Marin and Melkonian, 2010). The green flagellate genus *Mesostigma* may represent a very basal lineage of the charophyte clade (Charophyta), but some prasinophytes are likely representatives of even other early diverging clades (Fawley et al., 2000). With respect to the systematics of green algae, there is now consensus that the majority of known green algal species of the Chlorophyta belongs to three major lineages, the chlorophytes, trebouxiophytes, and ulvophytes, which are assigned to class rank (classes Chlorophyceae, Trebouxiophyceae, and Ulvophyceae; Pröschold and Leliaert, 2007). Green algae have an affinity to form symbioses with hosts of various phylogenetic positions. Well-known examples are green algae forming the photoautotrophic partners (photobionts) of fungal symbioses, that is, lichens, or representing the algal hosts (“Zoochlorellae”) of ciliates (Alveolates), heliozoa, sponges, and sea anemones (e.g., Summerer et al., 2008; Letsch et al., 2009).

Rhodophytes – red algae (Plantae supergroup)

Red algae are a very large and diverse group of microscopic algae and macroalgae. They are best known for their economic and ecological importance. Though they are present in freshwater with several genera, the majority of red algal genera occur on tropical and temperate marine shores, where they play important ecological roles (Graham et al., 2009). Certain calcified red algae, known as corallines, form hard, flat sheets

that consolidate and stabilize coral reef crests, that is, coralline red algae protect reefs from wave damage and, thus, they are regarded as important keystone organisms. Of well-known economic importance are the species of *Porphyra* and other red algal species which are grown in mariculture operations for use as human food. Several other marine genera are cultivated or harvested for the extraction of gelling polysaccharides such as agarose and carrageen (Graham et al., 2009).

Corallines are known from fossil records 500 million years old (Lower Ordovician; Riding et al., 1998). The oldest fossil record of a (non-coralline) red alga may represent the fossil taxon *Bangiomorpha pubescens* which was described from the 1,200-million-year-old Hunting Formation in the Canadian Arctic (Butterfield, 2000). It is most notable that *B. pubescens* even represents the earliest putative record for sex and taxonomically resolvable complex multicellularity among eukaryotes (Saunders and Hammersand, 2004). For a review of fossil records of the various taxonomic groups of red algae, see Saunders and Hammersand (2004).

The plastids of red algae lack chlorophyll *b* and *c*, but contain phycobilins (allophycocyanin, phycocyanin, and the red pigment phycoerythrin) as accessory pigments which are located in phycobilisomes on the outer surface of the thylakoids. The red algal plastids are bounded by two membranes and derived from a cyanobacterial primary endosymbiosis (Keeling, 2004). They produce floridean starch which is deposited in the cytoplasm. The rhodophytes lack flagella and centrioles in all stages of their life history (Graham et al., 2009).

The red algae (Rhodophyta) are a distinct eukaryotic lineage, whose members are united in the phylogenetic analyses of a nuclear, plastid, and mitochondrial genes (for review see Yoon et al., 2006). They belong to the Plantae supergroup of eukaryotes (Keeling, 2004) and are believed to form a sister group with the green line (Martin et al., 2002). Their divergence has been estimated ca. 1,500 million years ago (Yoon et al., 2004). Based on molecular evidence, the red algae are partitioned into seven classes, six of which have a rather simple body structure and reproduction (Yoon et al., 2006). The florideophytes (class Florideophyceae) are the monophyletic group of red algae that exhibit more complex bodies and reproduction (Saunders and Hammersand, 2004). The ecologically significant corallines, the economically important genus *Chondrus* (used as food and for the extraction of carrageen; Graham et al., 2009), and the vast majority of other modern red algal species are florideophytes; they are divided into several monophyletic groups (subclasses; Saunders and Hammersand, 2004; Le Gall and Saunders, 2007).

Coralline red algae represent not only a large carbon reservoir, but they also consolidate sediment and build landforms, and they occupy harder substrate in the

world's oceans than any other group of photosynthetic organisms. Unlike most other calcified algae that deposit carbonate as aragonite, the coralline red algae form calcite and it is believed that each family of coralline red algae is defined by only one crystalline modification of calcium carbonate (Borowitzka, 1977). The red algae show evidence of a surprising variety of calcification mechanisms, but the location of deposition is even more diverse. Mineralization may occur throughout the walls of nearly all vegetative cells, it may occur within the walls of only specialized cells, or it may be located in an intercellular organic matrix between cells, but not within the cell walls (Pueschel et al., 1992). Calcification in corallines is poorly understood, however, it seems clear that corallines deposit high magnesium calcite in a definitive pattern within their cell walls via the membrane pumps that control the flux of calcium and carbonate with the control of crystal orientation by organic wall components (Zankl, 2007). Coralline red algae can be the deepest algae (–50 to –110 m, Dullo et al., 1990) and many species occur in great abundance into the Arctic and subarctic. Coralline red algae in coral reefs are ubiquitous and dominant (Glynn et al., 1996; Keats et al., 1997), and their abundance in cryptic and shaded environments can be greatly underestimated (Littler, 1972). In temperate systems, the accumulation of unattached living or dead coralline algae forms large maerl beds (Martin et al., 2006). They also provide food for herbivores with hardened mouthparts (Steneck and Dethier, 1994) and surfaces for the settlement of invertebrate larvae (Adey, 1998). Coralline algal abundance, size, shape, and species composition in maerl beds vary considerably depending on their location, and several environmental factors influence coralline algal distribution. Maerl beds are highly sensitive to desiccation and are found from the low intertidal zone to depths of 150 m (Foster, 2001). Furthermore, coralline species are sensitive to seasonal variations in temperature inducing changes in their physiology, for example, *Lithothamnion* spp. growth rate increases with water temperature (Potin et al., 1990). Despite their ecological importance in temperate systems, primary production and calcification of coralline algae has been mainly investigated in tropical areas (Chisholm, 2003; Payri et al., 2001). A number of different associations between sponges and several species of red macroalgae have been described in literature (Trautman et al., 2000, 2002). The symbiotic association between the haplosclerid sponge *Haliclona cymiformis* and the red macroalga *Ceratodictyon spongiosum* is common on shallow coral reefs of the Indo-West Pacific, where it has been described as being one of the most conspicuous organisms found in these areas (van Soest, 1990). This symbiosis seems to be an obligatory association as neither sponge nor alga has ever been identified growing independently or in association with other species (Morrissey, 1980).

Glaucophytes (Plantae supergroup)

Glaucophytes (or glaucocystophytes) form a small group of microscopic algae exclusively found in freshwater environments; only about 13 species of glaucophytes have been described so far. They represent the third lineage of the plant supergroup, which is defined by plastids bound by a double membrane, that is, which is derived from primary cyanobacterial endosymbiosis (Keeling, 2004). Glaucophyte plastids are unique among plastids in that they are retaining the prokaryotic peptidoglycan layer between their two membranes. Therefore, they may represent an intermediate in the transition from a cyanobacterial endosymbiont to plastid; molecular phylogenetic analyses show the glaucophytes as the earliest divergence within the plant supergroup (Keeling, 2004; Martin et al., 2002). Glaucophyte plastids share the accessory photosynthetic pigments, phycobilins, which are organized in phycobilisomes (small particles on the outer surface of thylakoid membranes) with cyanobacteria and rhodophytes. For a review on glaucophytes, see Bhattacharya and Schmidt (1997) and Steiner and Löffelhardt (2002).

Photosynthetic stramenopiles (chromalveolates)

Stramenopiles form a monophyletic group of photoautotrophic as well as heterotrophic organisms which are characterized by swimming cells possessing at least one flagellum with distinct tripartite tubular hairs (Graham et al., 2009; Andersen, 2004). Most stramenopiles have two distinctly different flagella and, therefore, are also known as heterokonts. They have a long flagellum with tripartite hairs (tinsel or immature flagellum) to pull the cells through the water and a shorter smooth one (whiplash or mature flagellum) that lacks tripartite hairs, often with a light-sensing flagellar swelling at its base (Graham et al., 2009; Andersen, 2004). Photosynthetic stramenopiles or heterokont algae usually appear brown or golden brown (and are thus sometimes referred to as chromophytic algae) due to the presence of characteristic accessory pigments, fucoxanthin or vaucheriaxanthin, and at least one form of chlorophyll *c* (except in eustigmatophytes). The plastids are derived from a secondary endosymbiosis event with a red alga involved and surrounded by four membranes (McFadden, 2001; Keeling, 2004; Palmer, 2003). In most photosynthetic stramenopiles, a chloroplast endoplasmic reticulum is present, that is, plastid and nucleus are structurally connected. The photosynthetic stramenopiles comprise a tremendous morphological diversity: a large variety of unicellular or colonial algae, including the diatoms with silica frustules as walls, multicellular simple filaments (e.g., in the xanthophytes) as well as the macroscopic complex brown algae forming a brown canopy at sea shores. Based on detailed analyses of pigment composition, ultrastructure and molecular phylogenies more than a dozen of different classes of photosynthetic stramenopiles have been described (Graham

et al., 2009; Andersen, 2004). Some photosynthetic stramenopiles do not form mineralized cysts or scales and, therefore, they have no fossil record. Examples are the brown seaweeds (Phaeophyceae), the yellow green algae (Xanthophyceae), and the inconspicuous eustigmatophytes. In the context of geobiology also xanthophytes and eustigmatophytes may be important, as they have been reported from freshwaters with high calcite precipitation (see Figure 1g, e; Arp et al., 2010). However, their role in the calcification processes is still unclear. Therefore, in this entry, only those classes of photosynthetic stramenopiles will be discussed that produce mineralized cell coverings which are important in fossil deposits and, therefore, may be of particular interest in geobiology. Siliceous frustules define the diatoms (Bacillariophyta; see entry “*Diatoms*”), silica skeletons are characteristic for silicoflagellates (class Dictyochophyceae) and silica scales and cysts are commonly formed in synurophytes and chrysophytes.

Silicoflagellates are unicellular, flagellated, and photoautotrophic stramenopiles which are characterized in at least one life cycle stage by the formation of distinctive, one-piece external silica skeleton that is highly perforate. They form the order Dictyochaetales, one of three orders that have been described for the class Dictyochophyceae (Daugbjerg and Henriksen, 2001; Graham et al., 2009). Siliceous skeletons from silicoflagellates are common in fossil deposits dating back to the middle Cretaceous (ca. 120 million years ago). The skeletal remains in fossil material also indicate that species diversity reached a peak in the Miocene (ca. 23–25 million years ago), with more than 100 described species, but the diversity of silicoflagellates has decreased thereafter, leaving behind only two genera (Daugbjerg and Henriksen, 2001; Tappan, 1980). Biostratigraphic zonations have been developed for silicoflagellates in all oceans throughout the Cenozoic, though the zones typically range over longer intervals of time than foraminiferal or diatom zones (McCartney and Wise, 1990; McCartney and Harwood, 1992). Silicoflagellate skeletons may have considerable potential as ecophenotypic indicators (McCartney and Wise, 1990). Modern silicoflagellates are widespread in the oceans with a tendency to be more abundant in colder waters where they can even grow up to form blooms (Graham et al., 2009). Dictyochophytes occur in both marine and freshwater habitats (Moestrup, 1995; Moestrup and O’Kelly, 2000). *Synurophytes* and *chrysophytes* (often summarized as “Chrysophyte Algae”) produced an exceptional fossil record owing to the high preservation potential of their siliceous stomatocysts and scales (Smol, 1995; Andersen, 2004; Graham et al., 2009). In addition, they are highly sensitive to an array of limnological parameters. Synurophytes and Chrysophytes are close relatives in molecular phylogenies (Andersen, 2004); both share the capability to form stomatocysts, silica-walled resting stages, which arise sexually or asexually under unfavorable environmental conditions. The walls of stomatocysts

are so heavily silicified that they resist silica dissolution processes and thus accumulate in the sediments of lakes (Graham et al., 2009). Fossil records of stomatocysts extend back to the Lower Cretaceous (at least 150 million years ago). Synurophytes and chrysophytes are able to switch between autotrophy, heterotrophy, and even phagotrophy, which puts them at a distinct advantage in aquatic ecosystems that are low in nutrient concentrations and have reduced light penetration (Betts-Piper et al., 2004). From patterns of stomatocyst assemblages, past environmental conditions can be inferred making stomatocysts very important for paleolimnology (Duff et al., 1995; Siver, 1995; Wilkinson et al., 2001; Zeeb and Smol, 2001).

Synurophytes are unicellular or colonial silicated flagellates and despite they are photoautotrophic, many species are also capable of phagotrophy. Synurophycean cell surfaces are covered by overlapping silica scales, sometimes with spiny bristles, and are perforated (Graham et al., 2009). The scales’ perforation patterns are used as taxonomic features to delimitate species of synurophytes. A number of adhesive polysaccharides are involved in the scale attachment. The scales are produced in certain vesicles located on the surface of one of the plastids. In contrast to diatoms, synurophytes can continue to divide and function also in the absence of an external silica covering. In cultures of naked cells most cells will recover a complete cell covering when silicate is resupplied to silica-depleted cells (Leadbeater and Barker, 1995). Fossil scales similar to those of modern synurophytes have been reported from deposits of the middle Eocene (about 47 million years ago; Siver and Wolfe, 2005). Synurophyte scales can be used like stomatocysts for tracking environmental change using lake sediments (Zeeb and Smol, 2001; Wolfe and Perren, 2001). Synurophytes are abundant in neutral to slightly acidic freshwaters. Some species are regarded as indicators of low levels of pollution, but others are characteristic of eutrophic lakes (Graham et al., 2009).

Chrysophytes are golden-brown microalgae that are mostly unicellular or colonial which occur as flagellates or nonmotile cells; they include many unique and interesting morphologies (Graham et al., 2009). In contrast to synurophytes, scales covering the cell surface are absent in chrysophytes. Chrysophytes typically favor slightly acidic freshwaters of moderate to low productivity; their abundance and species richness increase with lake eutrophic status (Elloranta, 1995). Chrysophytes may have strong ecological impacts because many are mixotrophs, able to take up and metabolize dissolved organic compounds and particulate food as well as photosynthesize (Graham et al., 2009). Several chrysophytes are associated with the formation of undesirable blooms because living cells of certain species can produce toxic fatty acids that affect fish or excrete aldehydes and ketones into the water which can give it an unpleasant taste and odor.

Coccolithophorids and haptophyte algae (chromalveolates)

Haptophyte algae are a monophyletic group that includes all photosynthetic organisms with a haptonema. However, haptophytes also include some nonphotosynthetic relatives, and some that have secondarily lost the haptonema (Andersen, 2004). The haptonema, from which the group derives its name, is a microtubule-supported appendage that lies between two approximately equal flagella (for a review, see Inouye and Kawachi, 1994). Most haptophytes are marine, occurring in significant abundances even at greater water depth (up to 200 m). Haptophyte algae share many features, for example, pigment composition, presence of a chloroplast endoplasmatic reticulum, and plastids derived from red algal secondary endosymbiosis with the photosynthetic stramenopiles (Andersen, 2004). Based on structural and molecular evidences the haptophytes form a monophyletic lineage, treated as phylum Haptophyta which is divided into two classes (Edwardsen et al., 2000; Andersen, 2004). The larger group, class Coccolithophyceae, comprises the coccolithophorids which are haptophytes with a cell coat of mineralized scales (coccoliths) and two equal flagella or lack flagella altogether. Coccoliths are largely composed of calcium carbonate crystals in the form of calcite. There are two types of coccoliths, holococcoliths and heterococcoliths. In case of holococcoliths, an organic scale consisting largely of cellulose and produced by the Golgi body is secreted to the cell surface and then calcite crystals which are held together by organic material are deposited on the scale. In contrast, heterococcoliths develop on organic scales before being secreted from the cell, that is, calcite crystal deposition is already within the cell. The calcite crystals grow and interlock gradually forming the complex shape of the mature coccolith (deVrind-deJong et al., 1994; Probert et al., 2007; Graham et al., 2009). Coccoliths do not degrade at normal ocean pH and thus accumulate on the ocean floor. Therefore, coccolithophorids have produced huge amounts of sedimentary carbonates.

Coccolithophorids remove large quantities of atmospheric CO₂ through their photosynthesis and calcification and, therefore, are an important component of the global carbon cycle (McConnaughey, 1994), accounting for a substantial part of the ocean floor limestone sediments. Coccolithophorids contribute at least 25% of the total annual vertical transport of inorganic carbon to the deep ocean (Rost and Riebesell, 2004). Coccolithophorids have an excellent fossil record with fossil coccoliths well over 200 million years old. The abundance of coccolith fossils peaked during the late Cretaceous (63–95 million years ago) when extensive chalk deposits were laid down. Coccoliths are widely used as stratigraphic indicators and fossil coccoliths are widely used as bioindicators in the oil industry and as indexes of past climate and ocean chemistry conditions (Young et al., 1994).

Haptophytes are ecologically significant in terms of both biotic interactions and biogeochemistry. Haptophyte algae are considered as high-quality foods for zooplankton; several species contain nutritionally important polyunsaturated fatty acids which make them also commercially valuable for the production of fish in aquaculture systems. Other coccolithophytes may produce toxins that destroy cell membranes or produce copious amounts of organic slime and foam (Graham et al., 2009). Many coccolithophorids form blooms in ocean waters and produce large amounts of a volatile sulfur-containing molecule, dimethyl sulfide (DMS) that enhances cloud formation and increases acid rain (Malin and Steinke, 2004). Another cooling effect on the climate comes from the coccoliths which readily reflect light, thereby increasing reflectance of the ocean's surface.

Dinoflagellates (chromalveolates)

The dinoflagellates are an important group of phytoplankton in marine and freshwaters. Their adaptation to a wide variety of environments is reflected by a tremendous diversity in form and nutrition and an extensive fossil record dating back several hundred million years (Graham et al., 2009). Dinoflagellate cells have two structurally distinct flagella whose motion causes the cells to rotate as they swim, but also nonflagellate unicells and filamentous forms of dinophytes are known. Two different cell types can be distinguished on the basis of the cell-wall covering or theca. The “naked” or unarmored forms have an outer plasmalemma surrounding a single layer of flattened vesicles (membrane sacs or alveoli). Armored dinoflagellates have cellulose or other polysaccharides within each vesicle, giving the cells a more rigid, inflexible wall. These cellulose plates are arranged in distinct patterns which are extensively used as taxonomic “fingerprints” (Hackett et al., 2004). Cells of armored dinoflagellates display conspicuous anterior–posterior and dorsal–ventral differentiation. Their cells consist of two parts, separated by a groove that encircles the cell and contains the transverse flagellum which is flattened, ribbon-shaped, and with a single row of hairs. A smaller groove is mostly extending into the posterior cell part and contains the longitudinal flagellum which has two rows of hairs; it is directed posterior and emerges from the cell (Graham et al., 2009; Hackett et al., 2004).

Success of dinoflagellates as phytoplankton may be due in part to unique behavior patterns, including diel vertical migration and their capability to live phagotrophic (feeding on particles such as the cells of other organism) in addition to photoautotrophy (mixotrophic life-style). Some of the armored or thecate heterotrophic dinoflagellates have developed a remarkable pseudopod-like structure that is extruded from the cell and flows around the prey, enveloping it so the contents can then be digested (Hackett et al., 2004). Some dinoflagellates produce toxins that are dangerous to man, marine mammals, fish,

seabirds, and other components of the marine food chain (Van Dolah, 2000). Others are bioluminescent and emit light; some function as parasites or symbionts that rely on host organisms for part of their nutrition. Many photosynthetic dinoflagellates live as endosymbionts with reef-building corals. Stimulated by chemical signals from their animal hosts, dinoflagellate endosymbionts provide the corals with essential organic food.

Therefore, the dinoflagellate symbionts are critical components of the coral reef ecosystems whose loss during stress-related “bleaching” events can lead to mass mortality of coral hosts and associated collapse of reef ecosystems (Baker, 2003). Also, the high rates of calcification and production that characterize typically oligotrophic coral reef ecosystems are largely credited to the mutualistic symbiosis between the scleractinian corals and photosynthetic dinoflagellates belonging to the genus *Symbiodinium* (Apprill and Gates, 2007). Corals with a dinoflagellate symbiont calcify much faster than those without – an effect linked to photosynthetic fixation of CO₂ by the dinoflagellates (Marshall, 1996). A significant amount of photosynthetic product is excreted by the symbiotic dinoflagellates, primarily as glycerol. Up to 50% of the fixed carbon may be transferred to the host (Paracer and Ahmadjian, 2000), in which it is converted mainly to lipids and proteins. On the dinoflagellate side, many of these symbioses occur in oligotrophic waters in which nutrients are scarce in the water column (Hackett et al., 2004). In other symbiotic dinoflagellate associations, the hosts include foraminifera, radiolarians, flatworms, anemones, jellyfish, and even bivalve mollusks (Hackett et al., 2004).

Undisputed structural fossils of dinoflagellates occur some 200 million years or so ago (Graham et al., 2009). These fossils, known as hystrichospheres, resemble resting stages of some modern dinoflagellates. Some modern dinoflagellates produce resting cysts or zygotes with an organic compound resistant to decay and thus aid the survival of dinoflagellate fossils, of which a considerable diversity has been described (Fensome et al., 2003). Other chemical compounds thought to be specific to dinoflagellates have already been found in Proterozoic (Precambrian) rocks and such chemical fossils suggest that dinoflagellate-like organisms might have existed already more than 600 million years ago (Graham et al., 2009).

Many dinoflagellates are photosynthetic and, through endosymbiosis, have acquired a wide diversity of plastids from distant evolutionary lineages. The most common plastid in dinoflagellates is golden brown with a unique accessory pigment, peridinin; they also contain chlorophyll *c*. Such peridinin plastids are bounded by three membranes and are derived from red algal secondary endosymbiosis (Delwiche, 2007; Hackett et al., 2004). A number of dinoflagellates have plastids from haptophytes, diatoms, green algae, or cryptomonads which may have replaced preexisting peridinin plastids (tertiary endosymbiosis; McFadden, 2001; Keeling, 2004; Palmer, 2003).

A small group of dinoflagellates with peridinin plastids produce calcareous structures, formed during the life cycle or found in vegetative stages (Gottschling et al., 2005). The potential to produce calcareous structures has been considered as apomorphic within alveolates (Kohring et al., 2005), arguing for the monophyly of the family Calciodinellaceae which comprises approximately 30 (recognized) extant species that are distributed in cold through tropical seas of the world. Calcareous cysts are deposited in both sediments coastal (Montresor et al., 1998; Persson et al., 2000) and oceanic (Vink, 2004; Zonneveld et al., 1999). According to the fossil record, calcareous dinoflagellates originate in the Upper Triassic (Janofske, 1992) and are highly diverse during the Cretaceous and throughout the Tertiary (Keupp, 1991; Kohring, 1993; Willems, 1994), thus many fossil species (namely their cysts) have been described (Gottschling et al., 2005). Based on morphological and molecular data, calcareous dinoflagellates (Thoracosphaeraceae, Peridinales) are a monophyletic group comprising three major clades (Gottschling et al., 2008).

Other chromalveolates

Cryptomonads. Recent molecular phylogenetic analyses indicate that the cryptomonads and the haptophyte algae together form a monophyletic group (Hackett et al., 2007) and, therefore, also belong to the Chromalveolates supergroup. Cryptomonads form an abundant group of marine and freshwater unicellular flagellates that contain a plastid derived from red algal secondary endosymbiosis with chlorophyll *a* and *c* surrounded by four membranes. Cryptomonad plastids have received some attention because they are one of only two groups in which the primary algal nucleus has not been completely lost; they retain a small relict nucleus called a nucleomorph (McFadden, 2001; Keeling, 2004; Palmer, 2003).

Apicomplexa are a large group composed entirely of obligate intracellular parasites, including several that cause significant diseases such as malaria. As intracellular parasites, the discovery of a relict plastid (or apicoplast) in apicomplexa bounded by four membranes has drawn a great deal of attention as an evolutionary novelty and possible drug target (Keeling, 2004). There is current evidence indicating that this plastid is derived from a red alga and that the apicomplexa share a monophyletic origin with all other groups with plastids from red algal secondary endosymbiosis. The apicomplexa may be most closely related with the dinoflagellates (Moore, 2008). For a review of apicomplexa relating to their plastids, see Foth and McFadden (2003).

Algal groups with plastids derived from green algal secondary endosymbiosis

Chlorarachniophytes (Rhizaria supergroup). Chlorarachniophytes are a relatively rare group of marine amoeboid flagellates and flagellates that contain a green algal plastid (chlorophyll *a* and *b*) bounded by four membranes. They

contain a relict nucleus, nucleomorph, which has been retained from the green algal symbiont (McFadden, 2001; Keeling, 2004; Palmer, 2003). Chlorarachniophytes form a monophyletic group within the Rhizaria supergroup of eukaryotes (Ishida et al., 1999).

Euglenids (Excavates supergroup). Euglenids are a diverse group of common marine and freshwater flagellates, about half of which contain a plastid derived from green algal secondary endosymbiosis which is bounded by three membranes and contains chlorophyll *b* as accessory pigment. The remainder of the group are osmotrophs or heterotrophs that feed on bacteria or other eukaryotes. Molecular phylogenies show that photosynthetic euglenids may have acquired their plastids from a green alga relatively late in evolution, despite the Euglenozoa may be a rather old group. Euglenids are closely related to the parasitic trypanosomes (Kinetoplastids), together with diplomonids, making up the monophyletic Euglenozoa. Distinguishing features of euglenids are that they produce a storage carbohydrate which is a β -1,3-linked glucan (paramylon) in their cytoplasm and that they display a unique surface structure composed of parallel ribbon-like proteinaceous strips. For reviews of euglenids, see Leedale and Vickerman (2000), Milanowski et al. (2006) or Ciugulea and Triemer (2010).

Summary

Algae is a term of convenience and refers to a collection of highly diverse organisms that undertake photosynthesis and/or possess plastids. In addition, the photoautotrophic cyanobacteria are regarded as algae by some authors. In a recent phylogeny of the eukaryotes, the algae are scattered among four of the five recognized supergroups. A single primary endosymbiosis with a cyanobacterium may have been the start of all eukaryotic algae which first diverged into the green algae, red algae, and glaucophytes (Plantae supergroup). The plastids of all other algal lineages derived from secondary endosymbiosis involving either a red algal cell (algae of the Chromalveolates supergroup) or green algal cells (euglenids and chlorarchniophytes, Excavates and Rhizaria supergroups). Many algae form symbioses with ciliates and some metazoa. Algae are very important primary producers in almost every aquatic or terrestrial habitats and are important key players within the carbon and silica cycles for the major part of Earth history. Many lineages have produced significant fossil records due to their ability to precipitate calcium carbonate on their cell surfaces (red algae, some dinoflagellates) or form calcified (haptophytes) or silicified body scales, silica endoskeletons, resting stages, or cell walls (photoautotrophic stramenopiles, including dictyochophytes, synurophytes, chrysophytes, and diatoms). Due to their high sensitivity to certain environmental parameters and their high preservation potential, these algae also play important roles as sedimentary bioindicators in tracking environmental changes.

ALKALINITY

Andreas Reimer, Gernot Arp
University of Göttingen, Göttingen, Germany

The term “Alkalinity,” commonly denoted by TA (also A_T , ALK, and others) and then called titration alkalinity or total alkalinity, refers to a very important chemical concept in aquatic chemistry. Total alkalinity is one of the few measurable quantities in natural waters that allows, together with other properties, to calculate concentrations of single species of the carbonate system such as CO_2 , HCO_3^- , CO_3^{2-} , H^+ , and OH^- (Wolf-Gladrow et al., 2007), and further on, the saturation state of the waters with respect to certain carbonate minerals. Therefore, alkalinity represents a hydrogeochemical key parameter for the understanding of carbonate precipitation, either biologically mediated or not, and its variation through the geological history.

Definition

From its determination by titrimetric techniques, alkalinity has historically been defined as the number of equivalents of a strong acid required to neutralize 1 L of water at 20°C. The obtained end-point, corresponding to the second equivalence point of the carbonate system, was operationally defined and results were then commonly given as eq L^{-1} . The recent definition of alkalinity is based on the implementation of the Brønsted–Lowry concept of acids and bases by Rakestrow (1949) who defined alkalinity as the excess of bases (proton acceptors) over acids (proton donors). Considering seawater, alkalinity is mostly determined by the ions bicarbonate and carbonate, also by the borate ion, and to a smaller extent by OH^- and H^+ from

dissociation of water. Alkalinity then refers to the proton condition with reference to a zero level of protons defined by the species H_2CO_3 , $\text{B}(\text{OH})_3$, and H_2O , where the proton acceptors are HCO_3^- , CO_3^{2-} , $\text{B}(\text{OH})_4^-$, and OH^- and the proton donor is H^+ . That is, alkalinity is the equivalent sum of bases that have one or two protons less than the reference species minus H^+ (or H_3O^+) that has one proton more than H_2O (Dickson, 1981; Stumm and Morgan, 1996; Zeebe and Wolf-Gladrow, 2001). The expression for the total alkalinity is thus presented as

$$\text{TA} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{B}(\text{OH})_4^-] + [\text{OH}^-] - [\text{H}^+],$$

where conceptually the right hand term can be divided up in carbonate alkalinity ($\text{CA} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}]$) as the most dominant contributor, borate alkalinity, and water alkalinity.

Natural waters may contain various acid–base systems that can accept and donate protons other than or in addition to carbonic acid or boric acid. These complications have been taken into account currently in the most precise definition of total alkalinity of Dickson (1981) (compare also Dickson, 1992; DOE, 1994; and recent extension by Wolf-Gladrow et al., 2007). The definition is unequivocally based on a chemical model of occurring acid–base processes and to be independent of temperature and pressure expressed in gravimetric units (mol kg^{-1}). In Dickson’s concept, the total alkalinity (TA) is defined as the number of moles of hydrogen ion equivalent to the excess of proton acceptors over proton donors with respect to the proton condition defined by the value $\text{pK} = 4.5$ in 1 kg of sample. Bases formed from weak acids with a dissociation constant $K \leq 10^{-4.5}$ are considered proton acceptors, acids with $K > 10^{-4.5}$ are proton donors, and the chemical species defining the zero level of protons of the various acid–base systems are H_2CO_3 , $\text{B}(\text{OH})_3$, H_2O , H_2PO_4^- , H_4SiO_4 , NH_4^+ , H_2S , SO_4^{2-} , F^- , and NO_2^- . From this definition the expression for the total alkalinity is presented as

$$\begin{aligned} \text{TA} = & [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{B}(\text{OH})_4^-] + [\text{OH}^-] \\ & + [\text{HPO}_4^{2-}] + 2[\text{PO}_4^{3-}] + [\text{H}_3\text{SiO}_4^-] \\ & + [\text{NH}_3] + [\text{HS}^-] + \dots - [\text{H}^+] - [\text{HSO}_4^-] \\ & - [\text{HF}] - [\text{H}_3\text{PO}_4] - [\text{HNO}_2] \dots \end{aligned}$$

where the ellipses stand for additional acid–base species (Wolf-Gladrow et al., 2007).

An alternative definition for alkalinity derives when considering the charge balance of natural waters (Stumm and Morgan, 1996). From the principle of electroneutrality total alkalinity can be expressed in terms of the charge imbalance between the equivalent sum of conservative cations (base cations of strong bases) and the sum of conservative anions (conjugate bases of strong acids). For the total alkalinity of sea water dominated by

HCO_3^- , CO_3^{2-} , and B(OH)_4^- , the expression may be presented by

$$\text{TA} = [\text{Na}^+] + [\text{K}^+] + 2[\text{Mg}^{2+}] + 2[\text{Ca}^{2+}] \\ - [\text{Cl}^-] - [\text{Br}^-] - [\text{NO}_3^-] - 2[\text{SO}_4^{2-}],$$

which is equivalent to the above definition in terms of proton acceptors and donors

$$\text{TA} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{B(OH)}_4^-] \\ + [\text{OH}^-] - [\text{H}^+].$$

In the charge balance expression quantities are defined to be conservative with respect to mixing and changes in temperature (T) and pressure (P) provided that concentrations are on the gravimetric unit scale (mol kg^{-1}). Thus, from the TA expression entirely in terms of conservative ions TA is a conservative quantity too. In contrast, the concentrations of individual species of, e.g., the carbonate system may change with temperature and pressure because of the T - P dependency of the equilibrium constants.

Following the charge balance approach, Zeebe and Wolf-Gladrow (2001) and Wolf-Gladrow et al. (2007) have derived an expression in terms of total concentrations of conservative ions and conservative total concentrations of the various acid-base species under concern in the definition of Dickson (1981) in terms of an acid-base balance. This derived expression for TA is denoted as the explicit conservative alkalinity expression (TA_{ec}).

$$\text{TA}_{\text{ec}} = [\text{Na}^+] + [\text{K}^+] + 2[\text{Mg}^{2+}] + 2[\text{Ca}^{2+}] + \dots \\ - [\text{Cl}^-] - [\text{Br}^-] - [\text{NO}_3^-] - \dots \\ - 2\text{TSO}_4 - \text{THF} - \text{TPO}_4 - \text{THNO}_2 + \text{TNH}_3,$$

where total concentrations terms represent concentrations sums of the species of the acid-base systems $\text{TSO}_4 = [\text{SO}_4^{2-}] + [\text{HSO}_4^-]$, $\text{THF} = [\text{F}^-] + [\text{HF}]$, $\text{TPO}_4 = [\text{H}_3\text{PO}_4] + [\text{H}_2\text{PO}_4^-] + [\text{HPO}_4^{2-}] + [\text{PO}_4^{3-}]$, $\text{THNO}_2 = [\text{NO}_2^-] + [\text{HNO}_2]$, $\text{TNH}_3 = [\text{NH}_3] + [\text{NH}_4^+]$, and ellipses stand for additional ions with minor concentrations.

The definition of TA_{ec} has the advantage that each term in the expression is conservative with respect to T - P changes, even though single species in the total concentration terms may be not. In particular, the approach is very convenient to derive changes of TA due to certain physicochemical and biogeochemical processes such as nutrient uptake in biological production and release during remineralization.

Sources, changes, and ranges

The primary source of alkalinity in surficial (and subsurface) waters is carbonic acid-controlled chemical weathering of carbonates, aluminum-silicate minerals like feldspars or Mg-Fe-silicates. The overall concentration and subsequent changes in alkalinity of water are therefore determined by the geology of the watershed, the

predominant weathering reactions and ion exchange in the soils, and concomitant biogeochemical processes.

TA as a conservative quantity will first alter with changes in salinity as a result of precipitation, evaporation, and mixing. Contrariwise to its increase from dissolution of limestone carbonates TA decreases when biogenic or non-biogenic CaCO_3 or other carbonate minerals precipitate. Further important changes are due to various biogeochemical processes. It has to be noted that total alkalinity does not change as a result of CO_2 exchange with the atmosphere. Invasion or degassing of CO_2 affects the adjustment of the carbonate species (ratio of $[\text{HCO}_3^-]$ to $[\text{CO}_3^{2-}]$) and the pH but not TA. Therefore, it is also not the consumption of CO_2 during photosynthesis or release during aerobic respiration that brings about a change in TA, but the utilization or remineralization of nitrate and phosphate involved in the processes. Nitrogen assimilation in form of ammonia decreases TA and no change of TA results from molecular nitrogen uptake (Stumm and Morgan, 1996; Wolf-Gladrow et al., 2007). Several microbially mediated processes lead to a change in alkalinity where deviation in the charge balance is compensated by yield or consumption of H^+ or OH^- . When oxygen is consumed in processes like nitrification, oxygenation of soluble ferrous iron to ferric oxide or sulfide oxidation from HS^- or pyrite total alkalinity decreases. Under anoxic conditions, remineralization of organic matter by denitrification, reduction of iron and manganese oxides and sulfate reduction frequently result in large increases of total alkalinity (Lerman and Stumm, 1989; Stumm and Morgan, 1996).

Depending on the rock mineralogy of the catchment area and prevalent vegetation total alkalinity in streams and inland lakes commonly ranges below 3 mmol kg^{-1} . Very low alkalinity is bound to tributaries and lakes in crystalline rock areas or to acidic bog and peatland waters. Here, H^+ released by biomass exceeding H^+ consumption by soil weathering results in an excess of protons that is referred to as “mineral acidity” or in turn “negative alkalinity” (Stumm and Morgan, 1996). On the other hand, in hard-water creeks that gain their alkalinity preferably from the dissolution of limestone rocks TA may reach values of 4 mmol kg^{-1} to 6 mmol kg^{-1} close to their spring sites.

In the oceans, TA typically ranges from 2.2 mmol kg^{-1} to 2.5 mmol kg^{-1} where changes with depth are mainly associated with the production and dissolution of calcareous organisms (Broecker and Peng, 1982). Higher TA is found in today's only anaerobic ocean basin, the Black Sea, where alkalinity increases to about 4.5 mmol kg^{-1} in the anoxic bottom waters in the course of oxidation of organic material by sulfate reduction (Kempe, 1990; Hiscock and Millero, 2006). Also due to enhanced sulfate reduction and frequently complementing methane oxidation, TA in the order of $10^{-2} \text{ mol kg}^{-1}$ can accumulate in pore waters of marine sedimentary successions (Schulz and Zabel, 2000).

Even higher total alkalinity is typical for highly alkaline salt lakes, so-called soda lakes, which receive an equivalent load of HCO_3^- and CO_3^{2-} in excess to Mg^{2+} and Ca^{2+} from their riverine inflows. Here, TA can rise to

more than $10^{-1} \text{ mol kg}^{-1}$ and pH increase above 10 in the course of evaporation and subsequent Ca-carbonate precipitation while alkali cations, in particular sodium and potassium, increasingly maintain the charge balance of bicarbonate and carbonate ions (e.g., Lerman and Stumm, 1989; Kempe and Kazmierczak, 1994; Reimer et al., 2009).

Alkalinity and carbonate precipitation

Alkalinity, together with any of the three other measurable properties of the carbonate system – pH, dissolved inorganic carbon (DIC or $C_T = [\text{CO}_2] + [\text{HCO}_3^-] + [\text{CO}_3^{2-}]$), or PCO_2 (partial pressure of CO_2) – can be used to compute the remaining quantities including concentrations of

Alkalinity, Figure 1 (Continued)

single species such as HCO_3^- and CO_3^{2-} . From CO_3^{2-} and Ca^{2+} concentrations (or more precise activities) saturation with respect to carbonate minerals is determined, where saturation Ω is given by the product of the actual ion activities ($\text{IAP} = \{\text{Ca}^{2+}\} \times \{\text{CO}_3^{2-}\}$) divided by the solubility product of the carbonate (K_{mineral}) at ambient temperature and pressure ($\Omega_{\text{mineral}} = \text{IAP}/K_{\text{mineral}}$). A commonly used alternative notation is the saturation index (SI) which is defined as $\log \Omega$ ($\text{SI}_{\text{mineral}} = \log (\text{IAP}/K_{\text{mineral}})$).

The oceanic CaCO_3 saturation state is primarily determined by variation of the CO_3^{2-} ion concentration, because the Ca^{2+} concentration closely depends on salinity and does not vary substantially. In the upper ocean, CO_2 removal by primary production increases CO_3^{2-} concentrations resulting in an about fivefold supersaturation ($\text{SI} = 0.7$) with respect to calcite. On the other hand, biologically controlled calcification of calcareous plankton or reefal organisms is responsible for the lower alkalinity of about $2.2\text{--}2.3 \text{ mmol kg}^{-1}$ in surface seawater. In turn, supersaturation decreases with depth when CO_2 is released by remineralization of sinking organic matter when temperature and pressure changes. In the deeper ocean, total alkalinity then increases to about $2.4\text{--}2.5 \text{ mmol kg}^{-1}$ reflecting the dissolution of sinking calcium carbonate particles in response to the lower saturation state (e.g., Broecker and Peng, 1982; Morse and Mackenzie, 1990).

As one of the major factors in the oceanic carbonate system, alkalinity distribution and behavior in the oceans has thoroughly been investigated during the last decades. Dissolution-preservation patterns of biogenic carbonates in surface to deep oceans and the changes brought about by a rising atmospheric CO_2 level (Feely et al., 2004) have been assessed within global ocean research programs, as well as general feedbacks between the oceanic carbonate and the global climate system. Contrary to this rising knowledge on the modern marine environment, estimates

of ocean alkalinity throughout geological history are rare and, in the lack of direct analytical proxies, mainly rely on model assumptions. Ocean alkalinity comparably high as modern values is suggested for the Cenozoic and late Mesozoic (Tyrrell and Zeebe, 2004; Ridgwell, 2005). During periods of the Mesozoic and Paleozoic, alkalinity about two to three times higher than recent can be assumed according to the evolution of the Phanerozoic atmospheric CO_2 (Ridgwell, 2005), fluctuations in the rate of continental weathering (Locklair and Lerman, 2005), or the more widespread occurrence of anoxic basins (Kempe and Kazmierczak, 1994). Elevated alkalinity concentrations of some tenths of mmol kg^{-1} are suggested for the Earth's primordial ocean in favor of a slightly acidic to neutral Na-Cl-dominated chemistry under an early CO_2 -rich atmosphere (Grotzinger and Kasting, 1993; Morse and Mackenzie, 1998). Alternatively, even higher alkalinity has been postulated for a Precambrian alkaline "Soda Ocean" in analogy to modern Na-carbonate-dominated soda lakes (Kempe and Degens, 1985).

In principle, precipitation of CaCO_3 is kinetically unfavorable even at the fivefold supersaturation of the modern ocean (e.g., Morse and He, 1993). Mechanisms to overcome this kinetic inhibition evolved at the Precambrian-Cambrian boundary with the advent of controlled biomineralization that became a major regulator of carbonate precipitation since the Mesozoic proliferation of the calcareous plankton. Prior to the Cambrian, carbonate deposition was characterized by sea-floor encrustations, cement beds, and the widespread occurrence of microbialites (Grotzinger, 1990; Riding, 2000), which are attributed to calcification of biofilms and microbial mats. In the lack of direct metabolic control on carbonate production, these Precambrian deposits are thought to have been formed under the pressure of a higher supersaturated environment, possibly still accounting for the dominance

Alkalinity, Figure 1 Recent environments that sustain microbialite growth illustrated in terms of alkalinity behavior and carbonate mineral saturation. (a–c) Shark Bay in Western Australia is one of the few recent marine examples that sustains calcifying biofilms involved in the formation of agglutinated stromatolites. Here, Indian Ocean water entering the embayment and running over the Faure sill into the Hamlin Pool to the SE is concentrated upon evaporation (a, courtesy to NASA). According to the twofold increase in salinity, alkalinity, and carbonate supersaturation rises continuously (b). The famous Hamlin Pool stromatolites (c) occur in the southernmost bay where alkalinity has increased to more than 2.8 mmol kg^{-1} and waters are nearly ten times supersaturated with respect to calcite. (d and e) Today, microbialite growth is also sustained in environments such as hardwater creeks such as the Westerhöfer Bach (Shiraishi et al., 2008), which are commonly characterized by calcium-bicarbonate type waters. From take-up of soil CO_2 and subsequent subsurface dissolution of limestone rocks, these creeks have gained already high total alkalinities ranging from 4 to 6 mmol kg^{-1} . Otherwise, at their spring sites initial pH (around 7) and carbonate saturation ($\text{SI}_{\text{cc}} = 0$) are low due to partial CO_2 pressures much higher than the atmospheric level ($\text{PCO}_2 = 10^{-2} \text{ atm}$). Continuous physicochemical CO_2 -degassing along the flowpath increases pH and CO_3^{2-} and therefore enforces supersaturation (d). Precipitation of CaCO_3 and formation of calcareous microbialites, so-called tufa stromatolites (e), commences when supersaturation reaches a certain maximum threshold level of 10- to 15-fold ($\text{SI} = 1.0\text{--}1.2$) (Arp et al., 2001), and results in the subsequent decline of alkalinity and Ca^{2+} concentrations in the creeks. (f and g) The crater lake of Satonda Island (f), Indonesia, filled with water of nearly marine composition, represents the case of a subrecent microbialite formation obviously induced by an enormous increase of alkalinity in its anoxic deep waters (Kempe and Kazmierczak, 1990). The multiple salinity stratification of the lake is a residue of former evaporitic phases. Especially in the bottom layer, sulfate has nearly been consumed due to bacterial reduction resulting in an exceptionally high total alkalinity of more than 50 mmol kg^{-1} , sulfide concentrations of up to 12 mmol kg^{-1} , and extremely high PCO_2 (more than 10^{-1} atm) (g). Alkalinity and carbonate supersaturation in the photic surface layer is determined by the seasonal mixing transfer of alkalinity from the monimolimnion top layer to the mixolimnion, degassing, rain water dilution, and evaporation (Arp et al., 2003). In the surface layer alkalinity reaches twice the value of open marine waters (4.1 mmol kg^{-1}) and the tenfold supersaturation may constitute the prerequisite for the present-day, though minor, calcification of biofilms.

of microbial carbonates in the early to middle Paleozoic (Riding and Liang, 2005). Today, the occurrence of carbonate deposits comparable to ancient microbialites is confined to particular environments such as restricted evaporational marine settings, freshwater habitats like tufa stromatolite forming hardwater creeks, or alkaline salt lakes (Figure 1). Although at first glance very different, these environments in common exhibit a significantly higher alkalinity than recent ocean values and a 10–15 fold supersaturation (i.e., $SI = 1\text{--}1.2$) with respect to calcite. Maintaining elevated carbonate supersaturation as found in these recent environments and as suggested for certain periods in Earth's history calls for variation in alkalinity in paleo-ocean model calculations (Locklair and Lerman, 2005). Therefore, changes in alkalinity may be considered as an underappreciated hydrogeochemical key mechanism with regard to carbonate supersaturation and carbonate deposition in its various forms through geologic times.

Fossil resin; Resinite

Definition

Fossilized plant resin from various botanical sources.

Introduction

Amber is a fossilized plant resin from various botanical sources and of different geological ages, ranging from the Carboniferous to the Pliocene, although it is particularly frequent in the Cretaceous and in the Eocene to Miocene. The term “amber” is used most commonly as a synonym for fossil resin of every provenance, geological, and palaeobotanical source. A more reductive meaning of amber has been considered, referring only to *succinite*, the mineralogical species occurring in the Baltic coast deposits and neighboring localities containing significant amounts of succinic acid (up to 8%). However, most commonly, *amber* and *fossil resin* are the terms used interchangeably for indicating macroscopic material (Anderson and Crelling, 1995; Langenheim, 2003). Another term used by coal geologists for fossil resins is *resinite*, which is a microscopic material often found in coal maceral. Amber, fossil resin, and resinite, according to Anderson and Crelling (1995) should therefore be considered “solid, discrete organic material found in coals and other sediments as macroscopic or microscopic particles, which are derived from the resins of higher plants.”

The term amber derives from the Arabic word *anbar*, which was first used to indicate *ambergris* (a waxy substance secreted by the sperm whale, used in perfumery as a fixative) and then also fossil resin, both natural products with the common feature of being carried ashore by sea waves. The Romans called amber *succinum* (from *succus*, literally “juice,” “sap”). The ancient Greek name for amber is *elektron*, that means “shining thing,” a term which was related to the Sun God *Elektor* (the awakener), and the Moon, called *Elektris* (Stoppani, 1886). The modern term *electron* was coined in 1891 by the Irish physicist George Johnstone Stoney, using the Greek word for amber because static electricity could be generated on the surface of rubbed amber. The German word *Bernstein* (or *Börnstein*), the Dutch *Barnsteen*, and the Swedish *bärnsten* mean “burning stone” because amber may burn when exposed to flame.

Geological names are often attributed to fossil resins on the basis of the locality of discovery or of the discoverer, and these names are not based on specific knowledge of the composition; however, they are often used and also quoted in the scientific literature as common names. For example, *Simetite* is for amber collected in Sicily (Italy) near the Simeto river, *Burmite*, for amber found in Burma (Myanmar), and *Rumanite* for that found in Romania; *Beckerite* and *Stantienite* were named for Becker and Stantien, two developers of amber dredging and mining operations in the Samland region in the 1800s. Over a hundred of different fossil resins have been described, so far.

Fossil resins are considered the archetype of a “chemical fossil” (chemical evidence of life processes preserved in the fossil record), and besides their property of

preserving embedded organisms, they can also maintain particular details of their original composition better than any other sedimentary material.

Amber has been known by humans since prehistorical times and most bizarre hypotheses about its origin and composition have been formulated. In the antiquity amber has been considered even as produced by the rays of the Sun (Pliny the Elder, Book 37: *Nicias solis radiorum succum intellegi voluit hoc*) and that was not such a wrong idea, since amber, as a resin of ancient trees, is a metabolite of plants, originated from products of photosynthesis, that is, from the energy of the Sun.

Amber composition and formation

Several different parameters can play relevant roles in amber composition and consequently, they all should be considered in the study and comparison of different amber samples. These are for example:

1. *Original environment*: temperature, insolation, and climate influence the resin composition before it is embedded in the sediment (biostratonomic processes);
2. *Age*: complex chemical arrangements occur with time; in general, low molecular weight components disappear with increasing age;
3. *Plant source*: resin produced by different plants exhibit different chemical composition;
4. *Diagenetic history*: following the embedding in the sediment, resin maturation is affected by temperature, pressure and permeating fluids which can modify the chemical composition and the physicochemical properties of fossil resin;
5. *Alteration processes after amber mining* (of relevance especially in archaeological context): direct sunlight and exposition to air and heat may change the color and physical properties (and, consequently, the chemical composition) of the sample.

Resins consist of secondary components of plants, that is, chemicals occurring only in some groups of plants, without an apparent role in primary physiological or metabolic pathways. Most natural resins are derived from *terpenes*, a large and varied class of hydrocarbons, which are chemicals composed by structures based on the isoprene unit (C_5H_8) (Figure 1). The basic molecular formula of terpenes can be expressed as multiples of isoprene, $(C_5H_8)_n$, where n is the number of linked isoprene units. The isoprene units can link together “head to tail” to form linear chains, or alternatively they can arrange to form rings. The overall terpene structure undergoes oxidation or rearrangement of the carbon skeleton, producing compounds, which are generally indicated as *terpenoids* or *isoprenoids*. Mono-, sesqui-, di-, and tri-terpenoids are polymers formed by two, three, four, and six isoprene units, respectively.

The biosynthesis of resins starts from simple molecules, namely mevalonic acid, which can be considered the precursor of isoprene units. Photosynthetically

produced carbohydrates are broken down to give pyruvate, which represents the basis for the synthesis of mevalonic acid. Mevalonic acid is converted into the activated form of isopentenyl pyrophosphate, which gives origin to geranyl pyrophosphate (C₁₀), the basis for the monoterpene synthesis, or can further undergo condensation into farnesyl pyrophosphate (C₁₅) for the production of sesquiterpenes, or geranyl-geranyl pyrophosphate (C₂₀), which yields diterpenes and tetraterpenes, or squalene (C₃₀), which is the basis of triterpenes (Figure 2).

Fluid resins, after their exudation from plant, are characterized by a large volatile fraction, up to 50%, mainly constituted by monoterpenes and sesquiterpenes, while the nonvolatile fraction is composed of di- and tri-terpene acids (carboxylic acids with double bonds and functional groups), with alcohols, aldehydes, and esters. The volatile components of the resins are mainly involved in the defensive role of the resin against pathogens and insects. Evaporation of volatile components, following polymerization of the remaining nonvolatile constituents, mainly presenting dienic functions, causes the hardening of resin, which, if allowed to be embedded in appropriate sediment, poses the basis for transformation into a fossil resin.

Amber, Figure 1 The basic isoprene unit (C₅H₈).

Diterpenoid resins, mainly composed of diterpene acids (C₂₀), are produced by gymnosperms (conifers) and angiosperms (mostly in the Leguminosae family), and they are particularly prone to polymerization and thus being preserved during fossilization into amber.

Gymnosperm diterpenes are mainly represented by diterpene acids of the abietane, pimarane, and labdane types (Figure 3). Abietane- and pimarane-type diterpene acids, such as abietic and pimaric acids, abundant in the Pinaceae family, tend to remain unpolymerized; on the contrary, labdane-type acids (e.g., agathic and communic acids, common in the Cupressaceae family), easily polymerize thanks to conjugated diene compounds (Langenheim, 2003). Resins of the Araucariaceae family may contain all three diterpene groups.

Also the nonvolatile fraction of angiosperm resins, for example, from the genus *Hymenaea* of the Leguminosae (Fabaceae) family, which yields copal, is constituted by diterpenes of the labdadiene group. Resins from other angiosperms, such as Dipterocarpaceae, contain mainly triterpenes.

Therefore, resins containing particular diterpenes, such as abietic acid, cannot form amber *sensu stricto* because the constituent does not contain functional groups that could lead to a cross-linked polymer (Beck, 1999). Also triterpenoid resins (C₃₀), which are mainly produced by broad-leaved trees, generally do not polymerize.

The process of polymerization and resin hardening starts just after resin exudation, and involves free radical mechanisms, which are initiated by exposure to sunlight and air (Langenheim, 2003). Initial polymerization can

occur involving the terminal groups of a side chain in the molecule of terpenoids, mainly diterpenes with a labdanoid structure (unsaturated labdatriene acids and alcohols, and biformene), leading to the formation of a general polymeric structure (Anderson et al., 1992; Clifford and Hatcher, 1995; Clifford et al., 1997) (Figure 4). As a complex mixture, amber contains also nonpolymerizing compounds such as succinic acid in succinite, or monoterpenes, which are trapped (cross-linked) into the polymer network (Clifford and Hatcher, 1995; Clifford et al., 1997) and function as plasticizers.

Formation of amber occurs through the process of “maturation,” which is defined as the progressive changes of the resin occurring after the hardening and burial into the sediment, due to diagenetic and catagenetic processes. The chemical reactions in maturation of the resin to yield fossil resin include cross-linking, isomerization, and cyclization (Clifford and Hatcher, 1995; Clifford et al., 1997). One typical reaction in polylabdanoid fossil resins is the depletion of exocyclic methylenes (Figure 4) in the C8–C17 double bond of the molecule, and the formation of intramolecular cyclization. The modification of amber structure during its maturation leads to a progressive loss of unsaturated bonds, a decrease in functionalized groups and an increased proportion of aromatized groups (Grimalt et al., 1988).

Although the degree of resin maturation is dependent on the age of the resin, the rate at which this process occurs depends on several geological conditions, including the thermal history of the sample (Anderson et al., 1992) and on the structure and resin composition (Langenheim, 2003). Although a certain direct correlation between resin maturation and the age has also been demonstrated, by means of thermal analysis (Ragazzi et al., 2003), maturity and age cannot always be directly linked, since chemical transformation of resin increases at higher temperatures, and therefore the geothermal variable should be considered. Other physicochemical properties of amber, such as hardness and solvent solubility, may suggest the degree of maturation (Poinar, 1992; Rodgers and Currie, 1999; Langenheim, 2003; Ragazzi et al., 2003).

An alternative approach to define the age of a resin was proposed by Anderson (1997) on the basis of carbon-14 content. Resins that are older than the detection limit of carbon-14, that is, at about 40,000 years, have been considered *fossil resins*, and their age should be determined based on the stratigraphical data of the embedding sediment. Resins of age between 40,000 and 5,000 years are considered *subfossil*, while resins between 5,000 and 250 years are *ancient resins*, and those younger than 250 years are considered as *modern* or *recent*. This

Amber, Figure 4 Schematic representation of the polymeric structure in polylabdanoid fossil resins and of the maturation process (adapted from Clifford and Hatcher, 1995; Clifford et al., 1997).

terminology should be preferred to that referring to “young amber” or “copal,” which is often misleading with respect to the age of the sample.

Physicochemical characteristics of amber

Most amber pieces are minute ranging from millimeter to centimeter size. Resin pieces may be found preserved in their original shape as solidified in the amber forest (e.g., drops, elongate stalactites, lumps with a flattened side which was attached to the bark or to other surfaces). Fossil resin is sometimes still attached to fossil wood, or even *in situ* in wood or twigs which can help to identify the amber-bearing trees of a particular deposit. Amber pieces are more or less rounded after being transported and redeposited.

Amber has been extensively investigated under the physicochemical aspect. The relative hardness according to Mohs' scale is 2–2.5 (corresponding to 199–290 MPa) for most types of amber, indicating that it is slightly harder than gypsum and that it is possible to scratch the surface with calcite or copper. The specific

gravity, that is, the ratio of the density of a substance to the density of water, ranges from about 0.96–1.12. For this reason most amber is nearly floating in sea water (specific gravity of the Baltic sea water is very low, about 1.005) and it sinks to the bottom in quiet water, but it can easily be carried along by disturbed water and washed ashore. Because of its low density, amber floats on a salt solution (about 15 g of NaCl/100 ml), while several types of plastic, often used as amber imitation, sink due to their higher density (e.g., the phenolic plastic bakelite, which has a specific gravity of about 1.4). Amber has resinous luster, and might appear translucent or opaque. Its refractive index ranges between 1.539 and 1.545. The color of translucent amber varies from a honey-like yellow and yellow-orange to light and dark red; the latter color is often caused by weathering. Rare specimens of blue (e.g., some Dominican amber) and green (e.g., some Mexican amber) samples have been found. Resins may be opaque because of microscopic bubbles or tiny detritus particles. Sometimes, densely arranged filaments of bacteria and fungi

that grew into the resin in its liquid stage cause opacity of the outer parts of resin pieces (Figure 5). If exposed to ultraviolet light, amber often produces fluorescence of blue, yellow, or green color. When amber is heated, it becomes soft at 150–180°C and decomposes around 280–300°C, emitting fumes with aromatic odor. After touching amber with a hot needle (hot point test), it produces smoke and burnt-resinous odor; this method is empirically used to distinguish between amber and plastic or copal. Exposed to a flame, amber burns easily. Amber is insoluble in water, and partly soluble in organic solvents,

such as diethyl ether, acetone, and dichloromethane, as well as in mixtures of turpentine oil and acetone. After applying a drop of solvent to the surface, recent resins (copal) or plastic are readily dissolved and the surface becomes sticky, while amber (polymerized fossil resin) is unaffected. Although resin is macroscopically amorphous, some of its constituents may form microscopic drop- or bubble-like and elongated microstructures. Some of these “pseudoinclusions” may resemble enclosed microorganisms but can be distinguished by their variable size and shape and by the absence of diagnostic surface features (Figure 6).

Amber, Figure 5 Filamentous sheathed bacteria of ca 10 μm diameter preserved in French Cretaceous amber after growing into the liquid resin (photograph by Alexander R. Schmidt).

Chemical analyses and classification of amber

Since early chemical investigations in the nineteenth century, amber has been identified as being composed of carbon, hydrogen, and oxygen. It is not possible to indicate a univocal composition formula of amber since it is an amorphous, noncrystalline material. The composition of different types of amber, as a result of elemental analysis, has been indicated approximately in the following range: carbon 75–87%, hydrogen 8.5–11%, oxygen 5–15%, with traces of sulfur (up to 1.7%) and other elements (Kosmowska-Ceranowicz, 1984; Ragazzi et al., 2003).

Since amber is mostly insoluble in organic solvents, a complete characterization of its chemical composition has been obtained using the total solid sample, by means of specific analytical techniques that have become available, such as infrared spectroscopy (IRS), pyrolysis-gas chromatography/mass spectrometry (Py-GC/MS), and nuclear magnetic resonance (NMR) spectroscopy.

Amber, Figure 6 Pseudoinclusions in Cenomanian amber from Fourtou in the French Pyreneans (photograph by Alexander R. Schmidt).

Infrared spectroscopy of powdered samples, since the first application in the study of fossil resins (Beck et al., 1964), has become one of the main techniques for obtaining structural information and identification of amber from different origins (Kosmowska-Ceranowicz, 1999). Infrared spectra allow to define the fingerprinting of any fossil resin, and in particular it has been successful as diagnostic for Baltic amber, observing the presence of the characteristic Baltic shoulder in the 1,150–1,260 cm^{-1} region of the spectrum, attributed to the absorption of ester groups, in particular esterified succinic acid. It is noteworthy that the free succinic acid levels in Baltic amber range between 50 and 400 ppm (Tonidandel et al., 2009), despite the high total succinic acid content of 1–8%.

Anderson et al. (1992; also Anderson and Crelling, 1995), on the basis of various physicochemical methods, mainly Py-GC/MS, proposed a classification of fossil resins into five main classes:

Class I	The macromolecular structures are derived from polymers of primarily labdanoid diterpenes, which include labdatriene carboxylic acids, alcohols, and hydrocarbons
Ia	Derived from/based on polymers and copolymers of labdanoid diterpenes with regular [1S, 4aR, 5S, 8aR] configuration, including communic acid, communol, and succinic acid; example: succinite (Baltic amber)
Ib	Derived from/based on polymers and copolymers of labdanoid diterpenes with regular [1S, 4aR, 5S, 8aR] configuration, often including communic acid, communol, biformene, but not succinic acid; example: New Zealand's fossil kauri resin
Ic	Derived from/based on polymers and copolymers of labdanoid diterpenes with enantio [1S, 4aS, 5R, 8aS] configuration, including ozic acid, ozol, and enantio biformenes; examples: Mexican and Dominican amber, African resinates
Class II	Derived from/based on polymers of bicyclic sesquiterpenoid hydrocarbons, especially cadinene, and related isomers; examples: Utah and Indonesian amber
Class III	Natural (fossil) polystyrene; example: some New Jersey amber, Siegburgite from Germany
Class IV	Nonpolymeric, incorporating sesquiterpenoids based on the cedrane carbon skeleton; example: Moravian amber from the Czech Republic
Class V	Nonpolymeric diterpenoid carboxylic acid, especially based on abietane, pimarane, and isopimarane carbon skeletons; example: Highgate copalite and other retinites in European brown coals

The high-resolution NMR spectra of the carbon nuclei in powdered samples provided detailed information on the types of carbon functionality in the fossil resin, over the entire range of resonances, indicating the presence of

saturated carbons (resonances 0–100 ppm), unsaturated carbons such as alkenic and aromatic (resonances 100–160 ppm), and carbonyl groups (resonances above 160 ppm) (Lambert and Frye, 1982). Using NMR, comparative analysis of samples from different origin permitted to distinguish four major groupings (Group A through D) of fossil resins (Lambert and Poinar, 2002), in good agreement with Anderson's et al. classification based on Py-GC/MS.

Age, global occurrence, and botanical origin of amber

Amber might be found on every continent but most amber deposits have been discovered in the northern hemisphere, so far. A few ambers are known from South America, Africa, Australia, and New Zealand. Many new Mesozoic and Cenozoic amber localities have been described in the last decade (see Poinar, 1992; Grimaldi, 1996; Krumbiegel and Krumbiegel, 2005, for age and global occurrence of ambers).

A few resins were reported from the Carboniferous of Europe and the USA (Bray and Anderson, 2009). The first conifers which produced significant amounts of resin appeared in the Carnian stage of the late Triassic (about 220 million years ago). Remarkable amounts of small Triassic amber pieces have been found in the petrified forests of Arizona (Litwin and Ash, 1991), in the Molteno Formation of Lesotho (Ansorge, 2007) and the Heiligkreuz-Santa Croce Formation of the Italian Dolomites (Roghi et al., 2006, Figure 7). The latter is the oldest fossiliferous amber containing various microorganisms (Schmidt et al., 2006, see Figure 8). The Jurassic is particularly poor in amber and just few samples have been reported from the late Jurassic age of Portugal, Denmark (Bornholm), Germany, and Thailand.

The oldest Cretaceous ambers come from the Wealden Formation of southern England (Nicholas et al., 1993) and from the Kirkwood Formation of South Africa (Gomez et al., 2002), both being Valanginian in age. The most important fossiliferous Cretaceous ambers are (1) the *Middle East ambers* from Lebanon, Israel, and Jordan, ranging from the Hauterivian to the Aptian, (2) the Aptian–Albian *Álava amber* from Peñacerrada in the Basque county of northern Spain, (3) the *Siberian amber* from the Albian to Santonian of the Taimyr Peninsula, (4) the Albian–Cenomanian *ambers from Charente and Charente-Maritime* in southwestern France (see Perrichot et al., 2007, for these newly discovered ambers), (5) the *Burmese amber* from Myanmar which is Albian in age (Grimaldi et al., 2002; Cruickshank and Ko, 2003), (6) the *Atlantic coastal plain ambers* of the USA which comprise several localities of various Upper Cretaceous ages from Maryland and New Jersey to South Carolina, and (7) the Upper Cretaceous *Canadian amber* (Cedar Lake in Manitoba and other localities). Further remarkable Cretaceous resins come from Alaska, from several Albian to Coniacian localities in Japan, and from

Amber, Figure 7 Triassic amber drop from the Italian Dolomites (photograph by Guido Roghi, *Nature*, 444, 835, 2006). The piece is about 3 mm in length.

Amber, Figure 8 Shell of a testate amoeba enclosed in Triassic amber from Italy. This shell is 35 μm in size and morphologically identical to the modern species *Centropyxis hirsuta* (photograph by Alexander R. Schmidt, *Nature*, 444, 835, 2006).

the Aptian age of Golling in Austria, but these ambers yield few fossils.

Cenozoic ambers are largely Eocene to Miocene in age, and some deposits already produced tons of resin. The most well-known fossil resin is the *Baltic amber* which

can be found in the Baltic sea area (especially along the coast of Russia and Poland) in Eocene sediments, washed ashore and also as glacial erratic. The sediments bearing the Baltic amber are considered to be 38–47, some up to 55 million years old (Ritzkowski, 1999). Other fossiliferous Eocene ambers come from the *Paris Basin* in France (50–55 million years old; Nel et al., 1999), from Vastan (Gujarat) in western India (52 million years old; Alimohammadian et al., 2003) and from Fu Shun in the Chinese Liaoning province. The Bitterfeld amber from a coal mine near the city of Bitterfeld in central Germany is uppermost Oligocene in age (24 million years old, see Wimmer et al., 2006) and also produced a plethora of inclusions, mainly arthropods (Knuth et al., 2002). The most fossiliferous Cenozoic New World ambers come from the Dominican Republic and from Chiapas in Mexico (see Poinar, 1992). Recent studies suggest a Miocene age (15–20 million years old) for these Caribbean ambers (Iturralde-Vinent and MacPhee, 1996; Solórzano Kraemer, 2007). Further fossiliferous Miocene ambers were found in western Amazonia in Peru, and in Sicily and Borneo.

Representatives of various gymnosperm and angiosperm families have produced resin in the Earth's history (see Langenheim, 2003; Krumbiegel and Krumbiegel, 2005, for overview). The Italian Triassic amber was possibly produced by members of the Cheirolepidiaceae, an extinct gymnosperm family. Among others, various representatives of the Araucariaceae (Figures 9 and 10) and Cupressaceae are considered to be resin-bearing trees in the Cretaceous. Angiosperm resins are recorded since the Eocene, for example, *Glessite* stems from Burseraceae and *Siegburgite* were produced by Hamamelidaceae. The tropical genus *Hymenaea* (Leguminosae) produced the Dominican and Mexican ambers. The main resin-bearing trees of the Baltic amber forest probably belonged to conifers of the family Sciadopityaceae, as recently suggested by Wolfe et al. (2009).

Embedding and preservation of organisms in resin

Resins are produced by plants as defensive reaction against mechanical damage (injury to the bark, fire, herbivores) and potential invasion by pathogens, such as bacteria and fungi. Also, climatic reasons and ecological disturbance have been discussed to be the reasons for extensive resin production (Henwood, 1993).

The exceptional preservation of organisms included in amber is due to the dehydration environment made possible by the resin and by natural embalming properties due to antiseptic activity of the resin constituents. Components that do not participate in polymerization of the resin, such as some diterpene resin acids (e.g., copalic acid), can remain available for the interactions with biota embedded in resin (Henwood, 1993) and contribute to the preservation even of soft-bodied inclusions. Even cell organelles such as chloroplasts of algae are sometimes well-preserved in amber (Figure 11).

Amber, Figure 10 Extensive resin flows of ~30 cm length induced by fire at the bark of *Araucaria columnaris* in New Caledonia (photograph by Alexander R. Schmidt).

Extraction of ancient DNA from amber has been of particular interest in working with fossils embedded in amber, and in the early 1990s first attempts to establish methods for extraction, amplification, and sequencing of fossil

Amber, Figure 11 Preservation of chloroplasts in the conjugatophyte *Palaeozygnema spiralis* from the Cenomanian resin of Schliersee in the Bavarian Alps. The cells are ~15 μm in diameter (photograph by Alexander R. Schmidt).

DNA from amber were carried out (e.g., Cano et al., 1994; Cano and Borucki, 1995). However, critical reinvestigations suggest that the DNA obtained in these studies was modern contamination and because even the amplification of DNA from copal failed, Austin et al. (1997) concluded that resin is not predestined for the preservation of complex molecules, although morphological structures are recorded very well.

Attached to fresh sticky resin (Figure 10), organisms or parts of them are entirely covered by further resin flows. Amber inclusions are therefore usually found at the surfaces of successive resin flows in amber. Invertebrates of appropriate size, especially arthropods (e.g., diptera, hymenoptera, see Figure 12), and small plant remnants fallen onto the resin are therefore predestined for getting stuck and embedded. Arthropods, plant remnants (flowers, leaves, stellate hairs, wood, pollen, spores) and microorganisms are typical amber inclusions and sometimes, also small vertebrates (frogs, lizards) and parts of larger animals (reptile skin, feathers, hairs) are preserved. Some groups of organisms are only recorded as amber fossils, since few other fossilization processes occur in terrestrial environments which may preserve morphological structures even of soft-bodied organisms very well.

Many life forms and representatives of all trophic levels of a biocoenosis may be found in a single piece of resin: bacteria, algae as producers, protozoans, micrometazoans, molluscs, arthropods as consumers, and fungi as decomposers (Perrichot and Girard, 2009). Although many members of a biocoenosis can potentially become embedded in resin, selective embedding has been observed (Schmidt and Dilcher, 2007). Because of their motility, moving or flying arthropods have a higher probability of encountering and becoming attached to the resin. Therefore, the amount of amber inclusions of a species is not correlated with its abundance in the ancient ecosystem.

Most amber inclusions are fossils of terrestrial organisms which lived at or close to the resin-bearing trees. Much resin solidified at the forest floor, not on the bark (Henwood, 1993) and the term *litter amber* has been proposed by Perrichot (2004) for amber pieces which largely contain soil and litter-dwelling arthropods (Figure 13).

Amber, Figure 12 Hymenoptera (Scelionidae), fossilized in Lower Cenomanian amber of Fouras, Charente-Maritime, southwestern France. The inclusion is 1.8 mm in length (courtesy of Vincent Perrichot).

To find aquatic organisms in tree resin may seem to be highly unlikely but the fossil record provides amber-preserved limnetic arthropods (e.g., water beetles, water striders, crustaceans, larvae of caddisflies and mayflies) and microorganisms (e.g., algae, ciliates, testate amoebae, rotifers). Limnetic organisms may get stuck or enclosed when resin comes into contact with water or even flows into water (Schmidt and Dilcher, 2007).

Few amber inclusions of marine organisms (crustaceans, diatoms) have been reported from amber forests which grew directly at the coast (Vonk and Schram, 2007; Girard et al., 2008; see Figure 14). These organisms were probably introduced by wind or spray from beach and sea onto the resin flows in the nearby woods.

Although resin has fungicidal properties, some fungi and bacteria are able to grow into liquid resin and can therefore be found in almost every fossil resin. Usually, these filaments grow in random orientation as long as the resin is liquid. Growth stops when the resin solidifies and the filiform inclusions become well-preserved in the resin. Resinicolous fungi such as ascomycetes of the Mycocaliciales are adapted to their special substrates and are also able to grow on fresh resin. Therefore, they may be found in places where herbivore insects induce long-term resin flows (Rikkinen, 1999; Rikkinen and Poinar, 2000).

Resin which dried at the bark is exposed to the air, and processes of weathering and degradation start rapidly. Long-time preservation of resins and its inclusions and

formation of amber therefore generally needs redeposition into marine sediments or at least a cover by sediment layers to stop processes of oxidation.

Summary

Amber is fossilized plant resin, which is largely found in the Cretaceous and in the Eocene to Miocene when various representatives of gymnosperms and angiosperms produced considerable amounts of resin. After exudation from plants, the volatile components evaporate and the remaining nonvolatile constituents polymerize which leads to the hardening of the resin. Formation of amber occurs through the process of “maturation,” which is defined as the progressive changes of the resin occurring after the hardening and embedding into the sediment. The chemical reactions in the maturation of the resin to yield fossil resin include cross-linking, isomerization, and cyclization. Several different parameters can play relevant roles in amber composition, such as original environment, age, plant source, diagenetic history, and also alteration processes after amber mining. Inclusions of many life forms may be found in amber, although selective embedding has been observed. The taphocoenosis in a piece of amber may potentially contain organisms of different habitats such as tree bark, soil and litter, freshwater ponds, and littoral.

Definition

Anaerobic oxidation of methane (AOM): microbially mediated oxidation of methane to CO₂ by electron acceptors other than oxygen.

Introduction

Methane is the most abundant hydrocarbon in the atmosphere, and an important greenhouse gas (see *Methane, Origin*). A great deal of research has focused on the cause and climatic consequences of the variation in fluxes of methane to the atmosphere, throughout the Earth's history. Three key functional groups of microbial organisms play a central role in regulating the fluxes of methane on the Earth, namely the methanogens, the aerobic methanotrophic bacteria, and the more recently discovered anaerobic methanotrophic archaea (ANME). It is estimated that AOM is a major sink for methane on the Earth, and of similar relevance as its photooxidation in the atmosphere (Hinrichs and Boetius, 2002; Reeburgh, 2007).

Today, most methane is produced by methanogenesis, i.e., the final step in the fermentation of organic matter taking place in soils, wetlands, landfills, rice fields, freshwater and marine sediments, as well as in the guts of animals. Almost all of the methane produced in ocean sediments is consumed by AOM within the sulfate penetrated seafloor zones. Hence, the ocean does not contribute significantly to the atmospheric methane budget (<2%; Reeburgh, 2007). The first evidence for the removal of methane within anoxic sediments and seawaters came from

geochemical observations in the 1970s and 1980s (Reeburgh, 1969, 1976; Barnes and Goldberg, 1976; Martens and Berner, 1977). The involvement of sulfate as terminal electron acceptor was demonstrated by radiotracer measurements of methane oxidation and sulfate reduction in parallel incubations of undisturbed sediment samples (Iversen and Jørgensen, 1985). Field observations and experiments led to the hypothesis of a coupled mechanism, in which both methanotrophic archaea and sulfate-reducing bacteria (SRB) could profit from AOM, despite the generally low thermodynamic energy yield from this reaction (Hoehler et al., 1994). Finally, consortia of such microorganisms were detected in sediments from methane seeps, and the substantial depletion of their specific biomarkers in the stable carbon isotope ¹³C suggested that methane or a methane-derived compound is used as carbon source by these organisms (Hinrichs et al., 1999; Boetius et al., 2000; Orphan et al., 2001b). Till recently, all known anaerobic methanotrophs were clades related to the methanogenic Euryarchaeota termed ANME. In 2008, bacteria were found capable of oxidizing methane anaerobically with nitrate (Ettwig et al., 2008; 2010). In the past decade, much has been learned about the distribution, activity, and physiology of the ANME, however, not a single member of these groups has been obtained in culture and the biochemical functioning of AOM remains unknown.

The process of AOM

The AOM with sulfate as the final electron acceptor according to

is the major sink of methane in the oceans and hence a significant process in the global carbon cycle and methane budget (Reeburgh, 2007). Aggregated methanotrophic archaea (ANME) and SRB are assumed to act syntrophically (Hoehler et al., 1994; Hansen et al., 1998; Hinrichs et al., 1999; Boetius et al., 2000) where the archaeal partner activates and metabolizes methane, leading to an intermediate that is scavenged as electron donor by the sulfate-reducing partner. So far, there is no evidence for the involvement of extracellular intermediates such as hydrogen, formate, or acetate (Nauhaus et al., 2002; Boetius et al., 2008). The process of AOM with sulfate has been maintained in vitro in the laboratory and investigated with respect to substrate-product stoichiometry and dependence on pressure, temperature, and a variety of other environmental factors (Nauhaus et al., 2002, 2005, 2007; Girguis et al., 2003, 2005). The ANME doubling time was reported to be approximately 7 months, and the molar growth yield of AOM was 0.6 g cell dry weight (mol CH₄ oxidized)⁻¹. Corresponding to this estimate, only 1% of the consumed methane is channeled into the ANME biomass

(Nauhaus et al., 2007). Further steps toward an understanding of the metabolic pathway were the purification of a candidate enzyme (Ni-protein I) that may catalyze methane activation in a reverse terminal methyl-coenzyme M reductase reaction (Krüger et al., 2003) and genome-based observations of nearly all genes involved in methane production present in one specific ANME type (Hallam et al., 2004; Meyerdierks et al., 2009) both supporting the hypothesis that ANME carry out AOM by reverse methanogenesis.

Anaerobic methanotrophs

Discovery of ANME

Hinrichs et al. (1999) discovered a new archaeal group in sediments from a methane seep in the Eel River basin off California, together with characteristic archaeal lipid biomarkers strongly depleted in ^{13}C , indicating that methane must be the carbon source (Hinrichs et al., 1999). The dominant archaeal group was defined as ANME-1 and a second major group associated with was identified later as ANME-2 (Orphan et al., 2001a). Boetius et al. (2000) provided the first microscopic evidence for a syntrophic association of ANME archaea and SRB (Boetius et al., 2000). In both studies specific archaeal lipid biomarkers, i.e., archaeol, hydroxyarchaeol, crocetane, and pentamethylcosane (PMI), and bacterial lipid biomarkers common for SRB, i.e., *iso*- and *anteiso*- C_{15} fatty acids, were strongly depleted in ^{13}C . The first direct link between the identity and metabolic activity of ANME was provided by using a combination of ion microprobe mass spectrometry (SIMS) and fluorescence in situ hybridization (FISH) (Orphan et al., 2001b, 2002). These experiments confirmed the extreme ^{13}C depletion in the aggregate biomass, as predicted from the biomarker extractions. In 2006, a third archaeal ANME group, ANME-3, was discovered at the submarine mud volcano Haakon Mosby in the Barents Sea (Niemann et al., 2006b). Recently, a new clade of ANME-associated archaea (AAA) was identified in a bioreactor inoculated with sediments from a Dutch canal, but their relevance in freshwater and marine sediments remains unknown (Raghoebarsing et al., 2006; Knittel and Boetius 2009).

Diversity and morphology of ANME organisms

All yet known ANMEs are Euryarchaeota, and they form clusters distantly or closely related to the orders *Methanosarcinales* and *Methanomicrobiales*, which comprise a major part of the cultivated methanogens (Figure 1a).

The phylogenetic distance between the three ANME groups is large with 75–92% sequence similarity. Thus, members of ANME-1 and ANME-2 certainly belong to different orders or families, which have apparently similar physiological properties, i.e., the capability to oxidize methane anaerobically.

ANME-1 cells have a typical rectangular morphology and are autofluorescent under UV light, a feature characteristic for methanogenic archaea containing coenzyme F_{420} . ANME-1 archaea most often occur as single cells (Figure 2a) or in chains of two to four cells. In the Black Sea, “mat-type” associations of ANME-1 archaea and sulfate-reducing partners (Figure 2b) or ANME-1 and ANME-2 archaea (Figure 2c) form microbial mats (Michaelis et al., 2002; Knittel et al., 2005; Treude et al., 2007).

ANME-2 archaea belong to the order *Methanosarcinales*, but sequence similarity to cultivated representatives is below 90%. Similarity between subgroups, ANME-2a to ANME-2c, varies with an inter- and intra-group similarity of 75–90% and 90–100%, respectively. Diverse forms of associations between ANME-2 and their partner bacteria have been found (Figure 2d–k). Single ANME-2 cells were also reported (Figure 2d, l; Treude et al., 2007) as aggregated ANME-2 without any partner (Figure 2m, n; Orphan et al., 2002; Treude et al., 2007). In addition to the differences in phylogenetic origin, the two subpopulations ANME-2a and -2c could be distinguished from each other by their aggregate morphology. In general, ANME-2a/*Desulfosarcina* (DSS) aggregates represent the “mixed-type.” Here, archaea and SRB are completely mixed and the aggregates are not always spherical (Figure 2f–k). Typical ANME-2c/DSS aggregates represent the common “shell-type” with an inner core of ANME-2 which is partially or fully surrounded by an outer shell of SRB (Figure 2o–x). Sometimes SRB grow into the inner ANME-2c core, but they do not seem to mix completely (Figure 2u–w; Knittel et al., 2005). Microscopical analysis of a growing ANME-2 population showed that population growth occurred both as an increase in the number as well as in size of the shell-type consortia (Nauhaus et al., 2007). Starting from a few archaea and SRB cells, consortia seem to develop from smaller sized consortia to big aggregates of up to 100,000 cells (Holler and Knittel, unpublished data). Larger consortia separate evenly into two or unevenly into more aggregates when SRB grow into the archaeal colonies. The average diameter of consortia is 3–5 μm in situ with the smallest detected aggregate consisting of one ANME and one SRB cell and the largest 20 μm (Boetius et al., 2000; Knittel et al., 2005; Lösekann et al., 2007). Even much larger aggregates have been observed in enrichment cultures with >40 μm in diameter (Nauhaus et al., 2007; Holler, unpublished data). After reaching a specific size they appear to burst, releasing single cells into the environment (Figure 2ab).

The ANME-3 clade also belongs to the order *Methanosarcinales* and is closely related to cultivated species of the genus *Methanococcoides* with 95% 16S rRNA sequence similarity (Figure 1a). They form shell-type aggregates with a *Desulfobulbus* population as sulfate-reducing partner, however, only very few bacterial cells are associated (Figure 2y–z, aa).

Anaerobic Oxidation of Methane with Sulfate, Figure 1 (Continued)

Identification of ANME by methyl coenzyme M reductase gene phylogeny

The first genomic and proteomic analyses of sediments and microbial mats naturally enriched in the ANME biomass revealed a nickel protein similar to methyl coenzyme M reductase (MCR) as well as genomic fragments coding for nearly all genes typically associated with methane production. Based on these observations, earlier hypotheses on the role of reverse methanogenesis in archaea (Zehnder and Brock, 1979, 1980; Hoehler et al., 1994) appeared in a new light. Subsequently, molecular studies were conducted targeting the enzyme MCR, which catalyzes the terminal step in biogenic methane production (Shima and Thauer, 2005). Investigations have revealed a remarkably high phylogenetic diversity within *mcrA* genes among ANME archaea (Hallam et al., 2003; Inagaki et al., 2004, 2006a; Dhillon et al., 2005; Kelley et al., 2005; Alain et al., 2006; Lloyd et al., 2006; Nunoura et al., 2006; Lösekann et al., 2007) which have been classified into four subgroups (Hallam et al., 2003; Lösekann et al., 2007), group a–b (ANME-1), group c–d (ANME-2c), group e (ANME-2a), and group f (ANME-3) (Figure 1b). These groups are all distinct from those formed by methanogens. ANME *mcrA* gene phylogeny appears to be partially phylogenetically congruent to the 16S rRNA gene (Figure 3; Hallam et al., 2003; Nunoura et al., 2006; Lösekann et al., 2007). Quantification of specific ANME groups based on their *mcrA* gene abundance is now an alternative method to 16S rRNA based FISH to study distributional patterns of anaerobic methanotrophs in AOM zones (Nunoura et al., 2006).

Identification of ANME by their specific lipid biomarkers

Another molecular method, which has been crucial in the investigation of the natural distribution of ANME populations, is the identification of specific lipid biomarkers (see *Biomarkers*) and their stable carbon isotope signatures. This method can integrate phylogenetic information with function (^{13}C signatures indicating methane assimilation) and can be used for comparative analyses of community biomass. All three known ANME groups and their partner bacteria incorporate light (^{13}C -depleted) methane-derived carbon into their membrane lipids (Orphan et al., 2002; Niemann et al., 2006b). Using either naturally ^{13}C depleted methane (Nauhaus et al., 2007) or ^{13}C labeled methane as substrate (Blumenberg et al., 2004) for active populations of ANME in environmental samples have helped to identify typical membrane lipid

profiles. Crocetane is the only biomarker lipid specific for ANME, i.e., not found in methanogen cultures. Glycerol dibiphytanyl glycerol tetraethers (GDGT) were also used as indicator of ANME distribution (Schouten et al., 2003), but the ANME GDGTs appear to show some overlap with those of benthic Crenarchaeota, which often share the same niche in the seabed (Knittel et al., 2005). Recently, the biomarker approach was extended to include intact polar lipids (IPLs) which are of higher taxonomic specificity (level of families to orders) and property to select for living biomass (Sturt et al., 2004; Biddle et al., 2006; Rossel et al., 2008). Characteristic IPL molecular fingerprints have been reported for each specific ANME type: the lipids of ANME-1 archaea were dominated by diglycosidic GDGT derivatives, while IPLs of ANME-2 and ANME-3 archaea are dominated by phosphate-based polar derivatives of archaeol and hydroxyarchaeol (Rossel et al., 2008).

Bacterial partners of ANME

ANME-1 and ANME-2 archaea are usually associated with SRB of the SEEP-SRB I branch, subgroup a, of the *Desulfosarcina/Desulfococcus* (DSS) group (Figure 2; Schreiber et al., 2010).

These SRB are physically attached to the ANME-2 archaea, whereas ANME-1 is most often found without close physical association to other cells. The diversity within the SEEP-SRB1 cluster is high, and it is still unknown if the partners of the ANME-2a, -2b, and -2c subgroups belong to the same species. The morphology of the DSS cells varies from cocci (mostly associated with ANME-2c cells, Figure 2p–x) to rods (mostly associated with ANME-2a cells, Figure 2f–j). Other SRB have not yet been identified to be associated with ANME-1 and -2. ANME-3 archaea are most often associated with SRB of the *Desulfobulbus* branch (Figure 2), but have also been detected together with SRB of the *Desulfosarcina/Desulfococcus* group in shallow subsurface sediments of cold seeps from the Hydrate Ridge (Lösekann et al., unpublished data). Single cells of ANME-1, -2, and -3 have also been found in situ as well as in vitro enrichments, indicating that the physical association may be not obligate, but certainly the typical life mode of the anaerobic methanotrophs in most habitats.

There is also some evidence that the diversity of bacteria associated with ANME may be larger than anticipated. The analysis of ANME-2c consortia captured by whole-cell magneto-FISH showed a diversity of bacterial partners of ANME-2 far beyond the Deltaproteobacteria

Anaerobic Oxidation of Methane with Sulfate, Figure 1 Phylogenetic trees showing the affiliations of (a) anaerobic methanotrophic archaea (ANME) 16S rRNA gene sequences to selected reference sequences of the domain archaea. The tree was calculated with nearly full-length sequences (>1,300 bp) by maximum-likelihood analysis in combination with filters excluding highly variable positions. Data in colored boxes give information about the distribution and abundance of sequence retrieval and (b) ANME gene sequences coding for the alpha subunit of methyl coenzyme M reductase (*mcrA*) to selected sequences of the domain archaea. The tree was generated from deduced amino acid sequences (>247 amino acids) by neighbor-joining analysis with a 30% amino acid frequency filter. *mcrA* tree by courtesy of Lösekann. Bar, 10% estimated sequence divergence.

Anaerobic Oxidation of Methane with Sulfate, Figure 2 Epifluorescence micrographs of different ANME single cells and aggregates visualized by fluorescence in situ hybridization (FISH) or CARD-FISH. (a) Single ANME-1 cells living in a microbial mat from the Black Sea; (b) mat-type consortium formed by ANME-1 (red) and DSS cells (green); (c) aggregated ANME-1 (green) and ANME-2 cells (blue) in a microbial mat from the Black Sea; (d) single ANME-2a cells in an enrichment culture from Hydrate Ridge sediments; (e–k) mixed-type consortia of ANME-2a (red) and DSS (green) cells observed in different seep sediments; (l) single ANME-2a cells; (m) monospecific ANME-2a aggregate; (n) corresponding DAPI staining in an enrichment culture from Hydrate Ridge sediments; (o–x) shell-type consortia of ANME-2c (red) and DSS (green) cells of different sizes and structure observed in different seep sediments; (y–aa): ANME-3; (y) monospecific aggregation of ANME-3 at Haakon Mosby mud volcano, (z, aa) ANME-3/*Desulfobulbus* consortia; and (ab): DAPI staining of a large ANME-2c aggregate. Unless otherwise indicated, scale bar 10 μm.

Anaerobic Oxidation of Methane with Sulfate, Figure 3 Phylogenetic tree showing the affiliations of ANME-sulfate-reducing bacteria partner 16S rRNA gene sequences to selected reference sequences of the *Deltaproteobacteria*. The tree was calculated with nearly full-length sequences (>1,450 bp) by maximum-likelihood analysis in combination with filters excluding highly variable positions. Groups known as ANME partners are printed in boldface. Scale bar gives 10% estimated sequence divergence.

(Pernthaler et al., 2008). Lösekann et al. found evidence for ANME-3 aggregates with unidentified partners showing a mixed-type morphology in sediments from the Arctic mud volcano Haakon Mosby (Lösekann et al., 2007).

Habitats of ANME

Since their discovery, the distribution of the ANME organisms has been studied intensively, mainly based on 16S rRNA gene phylogeny. More than 1800 16S rRNA gene sequences are available now from more than 50 different marine methane seeps (Hinrichs et al., 1999; Orphan et al., 2001a; Aloisi et al., 2002; Tourova et al., 2002; Mills et al., 2003, 2004, 2005; Inagaki et al., 2004; Heijs et al., 2005, 2007; Knittel et al., 2005; Lanoil et al., 2005; Stadnitskaia et al., 2005; Arakawa et al., 2006a, b; Fang et al., 2006; Lloyd et al., 2006; Martinez et al., 2006; Niemann et al., 2006a; Nunoura et al., 2006; Reed et al., 2006; Lösekann et al., 2007), vents (Takai and Horikoshi, 1999; Teske et al., 2002; Kelley et al., 2005; Brazelton et al., 2006; Inagaki et al., 2006a), and “sulfate–methane

transition zone” (SMTZ) (Thomsen et al., 2001; Niemann et al., 2005; Parkes et al., 2007) differing in e.g., temperature, methane flux, salinity, and pH. Furthermore, the presence of ANME organisms in the water column (Black Sea; Vetriani et al., 2003; Schubert et al., 2006a) and in a terrestrial mud volcano in the Carpathian mountains (Romania; Alain et al., 2006) has also been reported. A comparison of these reports shows that globally, the two most abundant and diverse phylogenetic groups of methane-oxidizing archaea are the ANME-1 and ANME-2 clades. The distribution of ANME-2a and ANME-2c is as wide as for ANME-1, but only few sequences have been reported belonging to subgroup ANME-2b. ANME-2b, originally defined on the basis of few sequences as a separate group (Orphan et al., 2001a), now seem to be rather a subgroup of ANME-2a than a monophyletic group (Figure 1a).

Today it is known that ANME are present wherever methane and sulfate co-occur, at a wide range of environmental conditions (Knittel and Boetius, 2009). However,

usually only one specific ANME group dominates a habitat and seems to be responsible for most of the measured AOM (Knittel et al., 2005). High rates of methane oxidation, sulfate reduction, and/or sulfide production can be used as an indicator for high densities of ANME populations (Boetius et al., 2008). Continuous high fluxes of both AOM substrates methane and sulfate at mM concentrations sustain high cell densities of $>10^{10}$ ANME cells cm^{-3} in the environment and can even form some of the densest and largest cell accumulations known to exist in nature (Michaelis et al., 2002).

Seep ecosystems

Cold seeps form where tectonic or gravitational forces advect free gas, methane-rich porewater and/or mud upward into the sulfate-penetrated surface sediments and sometimes into the hydrosphere (Judd and Hovland, 2007; see *Cold Seeps*). The increased availability of dissolved methane at higher hydrostatic pressures increases the energy yield of AOM and leads to a natural enrichment of ANME populations. The products of AOM, sulfide and carbonate accumulate in the seabed, forming the typical features of cold seep ecosystems such as carbonate precipitates and high sulfide fluxes. The sulfide is oxidized chemically and microbially with oxygen, nitrate, or iron close to the seafloor surface. One of the most striking visual features of submarine cold seep ecosystems are mats of thiotrophic bacteria covering the seafloor. These mats are usually associated with high AOM rates and dense ANME communities inhabiting the underlying sediments (Sahling et al., 2002; Treude et al., 2003; Joye et al., 2004; Niemann et al., 2006b). Also, a variety of thiotrophic microbe–animal symbioses profit from AOM, such as siboglinid tubeworms and mytilid as well as vesicomyid bivalves (Sibuet and Olu, 1998). Thiotrophic mats and invertebrate symbioses may enhance the growth of ANME populations by rapidly removing the toxic endproduct sulfide, and by replenishing sulfate in the sediments (Treude et al., 2003; Cordes et al., 2005; Niemann et al., 2006b). In active cold seep sediments, AOM rates of $500\text{--}5,000\text{ nmol CH}_4\text{ cm}^{-3}\text{ day}^{-1}$ ($>2\text{ mol m}^{-2}\text{ year}^{-1}$) are reached, associated with very dense ANME populations of $>10^{10}$ cells cm^{-3} (Boetius et al., 2000; Knittel et al., 2005; Niemann et al., 2006b).

Cold seep ecosystems from Eel River Basin (Hinrichs et al., 1999; Orphan et al., 2001b), Hydrate Ridge (Boetius et al., 2000; Knittel et al., 2003, 2005), Black Sea (Thiel et al., 2001, 2003, 2007; Michaelis et al., 2002; Blumenberg et al., 2005; Reitner et al., 2005a, b; Treude et al., 2005a, 2007), Gulf of Mexico (Orcutt et al., 2005; Lloyd et al., 2006; Martinez et al., 2006), the Tommeliten and Gullfaks area in the North Sea (Wegener et al., 2008), and mud volcanoes from the Mediterranean Sea (Omorgie et al., 2008) and the Barents Sea (Niemann et al., 2006b; Lösekann et al., 2007) have been intensively studied. With the exception of cold seeps in the Black Sea (see next) most of the studies indicate a

dominance of ANME-2 or ANME-3. A prominent example is the gas hydrate bearing sediment from the Hydrate Ridge. Hot spots of ANME-2 are surface layers just above the gas hydrates with up to 10^8 aggregates cm^{-3} . Interestingly, ANME-2 subgroups revealed preferences for either *Beggiatoa* (ANME-2a) or *Calyptogenia* (ANME-2c) fields (Knittel et al., 2005) indicating that different environmental conditions select for different ANME groups.

Two seep systems are known yet where other ANMEs dominate: (1) sediments overlaying a brine pool methane seep in the Gulf of Mexico are dominated by ANME-1b archaea. Here, the ANME-1b community was found in the sulfate-methane interface, where low methane concentrations of ca. 100–250 μM are present and coexist with sulfate concentrations of ca. 10 mM; and (2) microbial mats from Black Sea cold seeps. These seeps are unique ecosystems and AOM is important both in sediments and in the water column (Pimenov et al., 1997; Wakeham et al., 2003). Tall reef-like structures composed of porous carbonates and microbial mats are found on the seafloor. These mats have been shown to mediate AOM and consist mainly of densely aggregated ANME-1 cells and SRB (Michaelis et al., 2002; Blumenberg et al., 2004, 2005; Knittel et al., 2005; Reitner et al., 2005a, b; Treude et al., 2005a, 2007). Treude et al. (2007) combined radiotracer incubations, beta-microimaging, SIMS, and CARD-FISH to locate hot spots of methanotrophy. Incorporation of ^{14}C from radiolabeled CH_4 indicated a hot spot for methanotrophy close to the mat surface associated with a dominance of ANME-1 archaea (Treude et al., 2007). The mats, however, are very heterogeneous and also provide niches for ANME-2. Black nodules from the top of the reef seem to be dominated by ANME-2 as shown by specific ^{13}C depleted lipids and FISH (Blumenberg et al., 2004). Reitner et al. found intracellular precipitation of iron sulfide (greigite) by bacteria growing in close association with ANME-2 and suggested iron cycling as an additional pathway involved in AOM (Reitner et al., 2005b).

ANME-3 archaea are commonly found at submarine mud volcanoes (Niemann et al., 2006b; Heijs et al., 2007; Lösekann et al., 2007; Omorgie et al., 2008) but also at other cold seeps (Orphan et al., 2001a; Inagaki et al., 2004; Knittel et al., 2005), hydrothermal vents (Brazelton et al., 2006), and recently in subsurface sediments (Parkes et al., 2007).

Sulfate–methane transition zones (SMTZ)

The most common ANME habitat on the Earth is the so-called SMTZ in the seabed (Thomsen et al., 2001; Ishii et al., 2004; Niemann et al., 2005, 2006a; Treude et al., 2005b; Parkes et al., 2007). SMTZ are found in all seabed horizons where the diffusive transport of methane from below and sulfate from above leads to a zone of AOM. Methane is completely consumed in the SMTZ, which may be found at decimeters to tens of meters below the seafloor (D'Hondt et al., 2004), depending on the depth

of the methane production zone, on the transport velocity of methane and sulfate and on their consumption rates. In diffusive seabed systems, the distribution of ANME is restricted to SMTZ. Population densities of ANME are low with $<10^6$ cells cm^{-3} (Niemann et al., 2005) and associated AOM rates are below $10 \text{ nmol cm}^{-3} \text{ day}^{-1}$ ($<0.04 \text{ mol m}^{-2} \text{ year}^{-1}$). The 16S rRNA gene libraries of ANME populations associated with SMTZ zones are very similar to those of cold seeps. The in situ dominance of ANME groups varies between the habitats. In SMTZ, sediments of Eckernförde Bay (German Baltic) ANME-2 archaea dominated (Treude et al., 2005b) as in the Skagerrak off the Danish coast (Parkes et al., 2007) or in a tidal sand flat of the German Wadden Sea (Ishii et al., 2004) while in the SMTZ of the Tommeliten seep area or at Hydrate Ridge ANME-1 were dominant (Niemann et al., 2005; Orcutt et al., unpublished data). Most likely, the SMTZ ANME archaea represent the seed populations for cold seep communities. It remains unknown whether SMTZ ANME possess special physiological adaptations to their energetically less favorable habitat compared to those at cold seeps.

So far, no ANME-related sequences have been published from the deep subsurface (D'Hondt et al., 2004; Newberry et al., 2004; Biddle et al., 2006; Inagaki et al., 2006b; Sorensen and Teske, 2006; Webster et al., 2006). Even in an extensive study by Inagaki et al. sequencing of several thousands of clones obtained from methane hydrate sites from Peru and Cascadia Margin did not result in the retrieval of ANME sequences (Inagaki et al., 2006b). Instead, archaea of the Marine Benthic Group B (MBGB, synonym Deep Sea Archaeal Group, DSAG) and the Miscellaneous Crenarchaeotal Group (MCG) were consistently the dominant phylotypes. Sediments lacking methane hydrates showed no or few MBGB phylotypes. The study by Biddle et al. supported these findings and suggested, based on stable isotopic compositions and intact archaeal lipids that these archaea assimilate organic carbon other than methane (Biddle et al., 2006).

Hydrothermal vents

High methane fluxes are also found at hydrothermal vents of mid ocean ridges (see *Hydrothermal Environments, Marine*), but these ecosystems may not offer many niches for ANME populations. The seafloor of mid ocean ridges consists of basalts and lacks a sediment cover, hence, the habitats for ANME-related organisms are limited to small anoxic zones within vent chimneys (Schrenk et al., 2004; Kelley et al., 2005; Brazelton et al., 2006). Furthermore, the fluids of most hydrothermal vents are sulfate free, and the seawater, which could provide sulfate, is oxygen rich – and hence toxic for ANME organisms. Temperatures range from $<40^\circ\text{C}$ to 90°C at pH 9 to 11. By contrast, sedimentary hydrothermal systems such as the Guaymas basin offer suitable habitats within the surface seafloor similar to the cold seep systems (Teske et al.,

2002; Schouten et al., 2003) although AOM accounts for $<5\%$ of sulfate reduction (Kallmeyer and Boetius, 2004). Another extreme environment in which ANME have been recently found is the CO_2 vented sediments of the Yonaguni Knoll hydrothermal field, southern Okinawa Trough, with an in situ pH <5 (Inagaki et al., 2006a).

Water column

The efflux of methane from cold seeps on the continental margin and mud volcanoes on the abyssal plain make the Black Sea the world's largest surface water reservoir of dissolved methane (Schubert et al., 2006b). Methane concentrations of up to $12 \mu\text{M}$ and AOM rates in the range of nM day^{-1} have been measured (Reeburgh et al., 1991). ANME-1 and ANME-2 archaea are suggested to be responsible for pelagic AOM in the Black Sea (Vetriani et al., 2003; Schubert et al., 2006a, b) accounting each for 3–4% of total cells (Durisch-Kaiser et al., 2005). ANME-1 and ANME-2 appear as single cells in anoxic water, compared to the sediment, where they most often form cell aggregates. Similar to the findings for sediments, one ANME-group dominates, i.e., below approximately 600 m water depth ANME-1 archaea and above 600 m ANME-2 archaea are suggested to be responsible for AOM (Schubert et al., 2006a).

Terrestrial habitats

The presence of ANME has also been reported for terrestrial habitats. ANME-2a archaea are the organisms responsible for AOM activity in a mud volcano field located in the Carpathian Mountains (Romania). Here, thermal alteration of sedimentary organic compounds leads to the release of methane and higher hydrocarbons into the environment (Alain et al., 2006). Additionally, presence of ANME-1 and -2 archaea in a freshwater lake has been reported (Lake Plußsee; northern Germany (Eller et al., 2005)). Long anoxic periods during the summer together with a high organic load in Lake Plußsee favor anaerobic processes in the sediment. In a distinct layer in the anoxic water body, low numbers ($<1\%$) of single ANME archaea were found.

Methane oxidation coupled to denitrification

Methane oxidation could theoretically also be coupled to electron acceptors such as NO_3^- , Fe(III) , and Mn(IV) . Recently, Raghoebarsing et al. (2006) demonstrated AOM coupled to denitrification of nitrate and nitrite in an enrichment culture according to

Anoxic sediment from the Twente canal in the Netherlands was used as inoculum to grow these organisms. The canal contained nitrate concentrations of up to 1 mM and the sediment was saturated with methane, which is typical for freshwater habitats receiving agricultural runoff. The bioreactor biomass was dominated by bacteria of the NC10 clade, a deep branching diverse phylogenetic group (Rappe and Giovannoni, 2003; Raghoebarsing et al., 2006). Recently, the genome of the dominant bacteria *Candidatus Methyloirabilis oxyfera* has been sequenced and surprisingly this apparently anaerobic, denitrifying bacterium encoded, transcribed and expressed the well-established aerobic pathway for methane oxidation, whereas it lacked known genes for dinitrogen production. Isotopic labelling experiments indicated that 'M. oxyfera' bypassed the denitrification intermediate nitrous oxide by the conversion of two nitric oxide molecules to dinitrogen and oxygen, which was used to oxidize methane (Ettwig et al., 2010).

Summary

The AOM is a key biogeochemical process on the Earth, and represents a globally important sink for methane. ANME are present in all environments where methane and sulfate overlap. Unfortunately, no member of the ANME groups or of their sulfate-reducing partner bacteria has been cultivated yet, and the biochemical process is not understood. As long as pure biomass of the archaea is missing, culture-independent molecular tools are the most helpful techniques to investigate the functioning of AOM, including metagenomics and proteomics. Protein patterns of different enrichments help in elucidating the most abundant and hence the most relevant proteins for both partners. Questions to the genome of both partners include for example, whether the ANME themselves may possess the genes for sulfate reduction, and what carbon and energy sources the sulfate reducers could utilize. Answering such questions from metagenomic data sets, however, remains difficult due to the relatively high diversity in the environmental enrichments, and the high proportion of open reading frames in the metagenomes which cannot be assigned to a certain functional category. Here, single cell technologies may provide solutions in the future.

ANAEROBIC TRANSFORMATION PROCESSES, MICROBIOLOGY

Bernhard Schink

University of Konstanz, Konstanz, Germany

Definition and Introduction

Microbial activities in geochemical processes are most often redox reactions, either between organic matter and inorganic compounds or between different inorganic compounds. In surface soils and lake sediments, organic matter typically derives from primary production by land plants or aquatic plants including algae, provided either directly or after primary digestion by animals. Underground soils and groundwater may receive major amounts of comparably stable organic matter, most often petroleum and its derivatives, through spills and accidents. Microbial oxidation helps to eliminate such contaminants, with concomitant reduction of inorganic electron acceptors. The surprising abundance of bacteria-like structures and even living bacteria in Deep Sea sediments and terrestrial rock material down to several 100 m below surface raised the question of how microbial life can be fuelled in the apparent absence of perceptible external substrate input. The

present overview will try to provide access for geoscientists and other nonbiologists to the concepts of microbial life in the anaerobic world in general.

The terms “anoxic” and “anaerobic” are often used simultaneously with more or less the same meaning. Anoxic means “oxygen-free” and refers to habitats, incubation conditions, etc. The term anaerobic contains the Greek root “bios” (life) and refers to microbes, microbial activities, enzymes, etc.

Organic matter as electron donor in geochemical processes

Organic matter as supplied by plant primary production consists mainly of carbohydrates, proteins, fats, and nucleic acids. Digestion by soil animals decreases the carbohydrate and protein fraction, and increases the content of polyanellated phenolic residues (humic compounds, Stevenson, 1994). The complete oxidation of carbohydrates at pH 7.0, using glucose as a representative molecule, yields electrons at $E_0' = -434$ mV on average (Figure 1a). These electrons are transferred inside microbial cells via specific electron carrier systems, most often via NAD^+/NADH , at $E_0' = -320$ mV. Other carriers operate at lower (e.g., ferredoxins around -420 mV) or higher (flavins, quinones, cytochromes; Figure 1b) redox

Anaerobic Transformation Processes, Microbiology, Figure 1 Redox potentials of (a) organic substrates, (b) biochemical electron carriers, and (c) natural electron acceptor/donor systems. Values taken or calculated from Thauer et al. (1977) and Zehnder and Stumm (1988). MQ menaquinone; UQ ubiquinone.

potentials, and finally all electrons may end up at the $\text{O}_2/\text{H}_2\text{O}$ -couple at $E_0' = +810$ mV (Figure 1c). Electron transport from low to high redox potentials provides chemical energy, which the cell conserves in energy-rich phosphoric acid anhydride linkages in the form of ATP which can be formed in the cell basically by two alternative processes (Thauer et al., 1977): In substrate-level phosphorylation, the transformation of a substrate molecule leads directly to an energy-rich intermediate from which ATP is formed in a stoichiometrically linked reaction. In electron transport phosphorylation, electron transport over a sufficient redox potential difference is coupled to the establishment of a proton (sometimes Na^+ ion) gradient across the cytoplasmic membrane which secondarily drives ATP synthesis via a membrane-bound ATP synthase reaction. Major steps in electron transport phosphorylation are the electron transports between NADH and the quinones, between quinones and cytochrome c, and between cytochrome c and oxygen (Figure 1b and c). In total, oxidation of glucose to 6CO_2 with oxygen as electron acceptor can yield up to 38 mol ATP per mol glucose (Fuchs, 2006).

Partial digestion of biomass leads to less energy-rich derivatives that are less valuable as electron donors. Incomplete oxidation and polymerization of aromatic and aliphatic plant matter residues forms humic compounds with a comparably long residence time of up to 100 years in soils. An average redox potential of humic compounds can be calculated with hydroquinone as a representative constituent, yielding a value at -280 to -300 mV. Fermentation of sugars and proteins produces acetate as the most important primary product; its oxidation yields electrons at -290 mV on average. Oxidation of aliphatic and aromatic hydrocarbons releases electrons at -240 to -270 mV. These examples illustrate that the typical constituents of partly digested or stabilized organic matter are less valuable electron donors in oxidation processes. Moreover, especially humic compounds and hydrocarbons are already comparably inert derivatives. Efficient degradation of these compounds requires molecular oxygen as a co-substrate in the initial oxygenase reactions for activation. Since oxygen-independent alternative reactions of activation of hydrocarbons (Widdel et al., 1993) or polyanellated aromatic compounds (humic compounds) are slow compared to the known oxygen-dependent ones, a major amount of organic matter (e.g., peat) is conserved in the absence of oxygen ("latch hypothesis"; Freeman et al., 2001).

The biogeochemical redox chain

Due to the low solubility of oxygen in water (about $300\text{ }\mu\text{M}$ O_2 in freshwater at air saturation and 10°C), aerobic oxidation of organic matter depends on a continuous supply of oxygen, either by plant photosynthesis or by convective transport from the atmosphere. Therefore, this oxygen supply is restricted to only few millimeters below the top surface in sediments or soils where only diffusive transport is possible. Under such conditions, other

electron acceptors can substitute for oxygen in its function as an electron acceptor, and the sequence of these subsequent redox processes is determined by the standard redox potentials of the individual redox processes (Zehnder and Stumm, 1988; Figure 1c). After oxygen consumption, nitrate is reduced first to nitrite, and afterwards either to N_2 via NO and N_2O , or to ammonia. In any case, nitrite is an important intermediate which may accumulate in laboratory experiments to toxic concentrations. In nature, nitrate concentrations rarely exceed $50\text{ }\mu\text{M}$ and nitrite never becomes toxic, therefore. As the redox potentials listed in Figure 1 indicate, nitrate reduction to N_2 (denitrification) appears to be energetically more feasible than nitrate reduction to ammonia (nitrate ammonification). However, some redox steps in denitrification are rather inefficiently coupled to ATP synthesis, thus wasting a considerable amount of energy and rendering nitrate ammonification the more efficient way of nitrate-dependent energy conservation (Strohm et al., 2007).

Subsequently, manganese(IV) oxides, e.g., MnO_2 (Braunstein), may be reduced to Mn^{2+} ions. The distribution of manganese oxides in soils is rather patchy; in lake sediments, it depends primarily on the chemistry of the catchment area. In Lake Constance, the eastern part of the lake receives ample supply of manganese oxides through the Alpine Rhine river whereas the western part of the lake is nearly devoid of manganese. Different from manganese, iron is a very dominant constituent of rocks and sediments, and can make up up to 1% of the total dry mass. Iron oxides, similar to manganese oxides, are nearly insoluble at neutral pH, and the redox potentials of Fe(III)-oxide reduction to Fe^{2+} -ions depends even on the individual iron(III) mineral involved ($+100$ mV with ferrihydrite, -287 mV with hematite; Widdel et al., 1993; Straub et al., 2005). The main problem in reduction of iron and manganese oxides is their apparent insolubility (Cornell and Schwertmann, 1996) and, with this, the necessity for bacteria to transport electrons to an acceptor outside the cell (see below).

Reduction of sulfate to sulfide is the dominant process of organic matter oxidation in marine sediments because seawater contains sulfate at high concentration (28 mM). Freshwaters contain far less sulfate ($50\text{--}200\text{ }\mu\text{M}$) rendering this process substantially less important at first sight. Nonetheless, sulfide can be reoxidized, e.g., with Fe(III)-oxides (see below) thus making reduction of sulfur compounds probably far more important in freshwater systems than assumed so far. The key problem in sulfate reduction is the initial reduction of the comparably stable sulfate molecule to sulfite which corresponds to a very low redox potential ($E_0' = -527$ mV) that cannot be fed directly with electrons from organic carbon oxidation. The sulfate reducers overcome this problem by ATP investment into this step, thus shifting the resulting redox potential to -60 mV (for details, see Cypionka, *Aerobic Metabolism*). The ATP required for this initial activation step is recovered in the further reduction of sulfite to sulfide.

Elemental sulfur is reduced by specific sulfur-reducing bacteria, but also by sulfate reducers. Elemental sulfur is easy to reduce and does not require prior activation. The problem of sulfur metabolism is again its low solubility in water which may be circumvented by the intermediate formation of water-soluble polysulfides in the presence of the formed hydrogen sulfide.

The terminal process in organic matter degradation in freshwater environments is the formation of methane, either by reduction of CO_2 or by cleavage of acetate (Wolfe, 1992; Thauer, 1998); alternatively, acetate may be formed first by CO_2 reduction, and secondarily be converted to methane (Drake et al., 2002; K. Kuesel, this series). Since the methanogenic archaeobacteria are restricted to the use of only very few substrates (H_2 , C_1 compounds, and acetate) complex organic matter has to go through fermentations by several groups of specialized bacteria (Schink, 1997) before it finally ends up in a mix of CH_4 and CO_2 , i.e., in complete dismutation of the carbon atoms.

Hydrogen is an important product of microbial fermentations of organic matter. It can be formed as well by geochemical processes and may be a source for microbial life in deep sediments and rocks.

The middle axis in Figure 1 (b) positions the key elements of the biochemical electron transport chain between organic matter on the left and the various acceptor systems on the right. This arrangement illustrates the major paths of electron flow in microbial transformation processes. One should emphasize, however, that biological systems are able to shift electrons also against the “normal” electron flow by “reversed electron transport” at the expense of energy supplied by transport of other electrons in the “normal” direction from negative to positive potentials. The scheme illustrates that glucose is comparably a valuable electron donor whereas the electrons derived in degradation of acetate, humic compounds, or hydrocarbons cannot all be transported via NADH, rather, many of them have to enter the transport chain at the level of quinones (either menaquinone or ubiquinone) with the consequence that substantially less ATP is formed. The scheme also illustrates that, e.g., reduction of ferrihydrite can be fed with electrons only at the potential of quinones, and that necessarily the ATP yield of this process is much smaller than, e.g., that of the reduction of nitrate or oxygen. It also becomes evident that phosphate can hardly be reduced to phosphine in a respiratory process, analogous to sulfate or nitrate reduction, but would require substantial amounts of energy rather than yield energy. The origin of traces of phosphine in certain anoxic environments is still unclear; it probably derives from corrosion of iron phosphides in scrap metals (Ding et al., 2005).

Lithotrophic reoxidations

The reduced derivatives formed in the processes above during oxidation of organic matter can act again as electron donors in microbial energy metabolism, e.g., if H_2S ,

reduced Fe^{2+} , or Mn^{2+} diffuses upwards and meets electron acceptors of higher redox potential, thus again creating a redox couple that can yield energy. Such metabolic activities are called “lithotrophic” (Greek *lithos* = rock) because in this metabolism inorganic electron donors serve as electron source. A lithotrophic metabolism is most often, but not necessarily, combined with autotrophic fixation of CO_2 into cell material, i.e., bacterial growth. Obviously, synthesis of organic matter from inorganic sources has to be fueled by energy (ATP) that is derived, in this case, from inorganic redox processes. Therefore, the yield of organic matter, i.e., of microbial cell mass, in these processes is usually small. As the redox chain in Figure 1c illustrates, H_2 , H_2S , and Fe^{2+} are good electron donors whereas nitrite, selenite, and Mn^{2+} are not. Behind every such redox process stand the activities of specialized bacteria and archaea which try to exploit every fraction of energy that can be derived from these redox processes.

An exceptional case is methane oxidation which can proceed either with oxygen as a co-substrate and an electron acceptor, yielding a huge amount of energy or with sulfate as electron acceptor (anaerobic methane oxidation; see Boetius, *Anaerobic Oxidation of Methane with Sulfate*) yielding extremely little energy. Similar problems apply to higher aliphatic or aromatic hydrocarbons (Spormann and Widdel, 2000).

Oxidation of sulfide with ferric oxides should yield energy as well. Nonetheless, this reaction proceeds spontaneously as a chemical reaction (see below), and so far there is no indication for microbial activity exploiting this redox reaction.

Energetics

Bacterial growth requires energy which is derived from substrate conversions in the form of ATP. Irreversible synthesis of the energy-rich acid anhydride linkage of ATP by condensation of ADP with a phosphoryl residue under the conditions prevailing in living cells requires energy (ΔG^0 or Gibbs free energy) in the range of 60–70 kJ per mol (Thauer et al., 1977; Schink, 1997). Nonetheless, metabolic energy can also be converted into ATP at smaller increments. The membrane-bound ATPase enzyme mentioned above catalyzes the synthesis of ATP reversibly with a translocation of protons or Na^+ -ions; the stoichiometry is 3–4 H^+ or Na^+ ions per ATP. Thus, any reaction that can be coupled to the translocation of protons or Na^+ -ions across the membrane can be associated with ATP synthesis, down to reactions transferring only 1 H^+/Na^+ , equivalent to an ΔG^0 in the range of 15–20 kJ per mol. Of course, reactions can proceed also with lower energy yields, but then they cannot feed ATP synthesis and bacterial growth. Growth, on the other hand, is a very important means to maintain a degradative capacity in a certain environment and to adjust its activity to the local needs (different from so-called “co-metabolic” activities which are not positively correlated with bacterial growth; McCarty, 1988).

Extracellular electron transfer

Electron transfer from or into the electron transport chain (Figure 1b) is easy with substrates that can be taken up into the bacterium in a dissolved form. Non-dissolved substrates have to be oxidized or reduced outside the cell, either at the immediate cell surface or via dissolved electron carriers. The reduction of ferric iron oxides can be accomplished in direct contact with the bacterial cells; perhaps, even small cellular appendages can act as “nanowires” for electron transfer (Reguera et al., 2005). Alternatively, either dissolved humic compounds (Lovley et al., 1996) or low-molecular weight quinoid or phenazine compounds may act as electron carriers (Hernandez et al., 2004). As a further alternative, sulfur-reducing bacteria can indirectly reduce iron via H_2S at low (<0.1 mM) concentration (Straub and Schink, 2004). At low H_2S concentration, H_2S delivers electrons to ferric oxides and is converted to a more oxidized species, perhaps thiosulfate or polysulfide, which is reduced again by the bacterium. In this case, a small sulfur cycle acts as an electron delivery system. One should emphasize that in the latter cases, the bacteria do not actually reduce the ferric oxide. They reduce quinoid or sulfur compounds, and the ferric oxides are reduced indirectly in a subsequent unspecific reaction. Such secondary electron transfer reactions may be important also with respect to other reductive transformations such as nitro group reduction, dehalogenation, etc. (Holliger et al., 1997).

The example of indirect ferric iron reduction via sulfur compounds appears to contradict the generally accepted preference of biochemical redox processes according to the sequence mentioned above: since the redox potential of the iron(III)/ Fe^{2+} -couple is higher than that of the sulfate/sulfide system, iron should be reduced before the sulfur compounds. Nonetheless, for bacteria not only the redox potentials but also the bioavailability aspect counts: since the sulfur compounds are easier to access they may be preferred over the insoluble iron oxides.

Phototrophic activities

Photosynthesis as performed by green plants and algae is called oxygenic because molecular oxygen is released from water through the activity of two combined light reactions. This biochemical potential was evolved by cyanobacteria (formerly called blue-green algae) and the evolution of oxygenic photosynthesis has changed the chemistry of our planet around 3.5 billion years ago in a most dramatic way from a reducing to an oxygenated atmosphere. The massive precipitation of iron oxides in the so-called “Banded Iron Formations” has for long times been considered to witness the evolution of molecular oxygen in the Earth’s atmosphere, but the oxygen thus evolved would have been consumed to a large extent over several hundred million years in the oxidation of Fe^{2+} to ferric oxides. Anoxygenic phototrophic bacteria perform a simpler, older type of photosynthesis from which oxygenic photosynthesis was later derived. The discovery of

Fe^{2+} -oxidation by anoxygenic phototrophs (Widdel et al., 1993) changed also our understanding of the development of Banded Iron Formations; this process became possible also without the involvement of molecular oxygen, and thus formation of Banded Iron Formations could now testify only the evolution of anoxygenic, rather than of oxygenic photosynthesis (Kappler et al., 2005).

Spatial/seasonal oscillations

Many microbial habitats such as the Deep Sea and its sediments, or rocks in the deep underground are highly stable systems which do not change their properties over many thousands or millions of years. On the other hand, microbial life conditions in a top soil may change dramatically with every rainfall, and bacteria inhabiting the sediment surface in a shallow, light-exposed lake may undergo dramatic life changes in diurnal cycles of light and oxygen supply which are probably the most dramatic changes for living systems at all. As shown in Figure 2, oxygen profiles during light exposure versus darkness show dramatic differences with respect to the oxygen concentration and to oxygen penetration depth into the sediment. Other parameters change over longer time scales, e.g., with seasons. Figure 3 shows a section of the littoral sediment of Lake Constance in January when the water level is low.

Anaerobic Transformation Processes, Microbiology, Figure 2 Distribution profiles of oxygen in littoral sediment of Lake Constance under the influence of different light conditions. (x) 12 h dark, (+) 12 h incubation at low light, equivalent to an overcast day, (*) 12 h incubation at high light intensity, equivalent to a sunny day. Incubation basins were exposed to light under a 12 h-light-dark cycle with three Osram lamps Biolux (L30W/72), Fluora (L30W/77), and Haloline (200 W/R7s) to generate high light intensity of 15 kLux ($250 \text{ E m}^{-2} \text{ s}^{-1}$) at the water surface.

Anaerobic Transformation Processes, Microbiology,

Figure 3 Leaching of ferrous iron from littoral sediment of Lake Constance in Winter 2002. Fe^{2+} ions leach from the upper right part to the left, with continuous chemical/microbial oxidation of Fe(II) to Fe(III) oxides.

The higher regions of the sediment (which are under water through the major part of the year, with annual water level changes of 2.5 m) are exposed to air in wintertime, and the reduced Fe^{2+} leaches out of the sediment to be oxidized to Fe(III) oxides. Of course, such water level fluctuations influence all life forms in the littoral sediment, beyond the normal fluctuations of light and dark in the day cycle, and of temperature through the annual cycle. The microbial community within the sediment either has to adapt to these changes as far as possible or has to migrate within the sediment to maintain a stable life situation.

Conclusions

Microbes are magnificent chemists. They catalyze reactions that are thermodynamically feasible, but enhance them kinetically as any good catalyst does. Beyond that, they can couple exergonic reactions in their energy metabolism with endergonic processes in their assimilatory metabolism in a way that chemical processes could never accomplish. Through bacterial growth, the catalytic potential is adjusted at a certain site to the local needs. Many processes are strongly accelerated by the action of microbes, and the total extent of their activities in Deep Sea sediments and in the deep underground can so far only roughly be estimated. Nonetheless, there is little doubt that microbes in the underground make up a significant part of living protoplasm on Earth in general, ranging in the same order of magnitude as that of plants and animals together (Whitman et al., 1998). The fascinating efficiency with which microbes catalyze chemical processes into impressive dimensions (as, e.g., in the precipitation of the Banded Iron Formations) gives us only a vague idea of the importance of microbial catalysis in the geochemistry of our planet. Geochemists and geomicrobiologists have to join their forces to understand the action of microbes in highly structured environments that appear extremely

poor with respect to utilizable energy sources, in order to assess the contributions of life to geochemistry correctly.

GRN. Gene regulatory network

Introduction

One of the major events in the evolution of multicellular animals was the transition from soft-bodied organisms to those that possessed mineralized hard parts for protection

and support. This major evolutionary hallmark supported the rapid diversification of animals and their occupation of a diverse range of novel ecological niches at the dawn of the Phanerozoic, between 560 and 530 million years ago, when mineralized skeletons appeared relatively synchronous in a variety of Phyla during the so-called Cambrian Explosion (Knoll, 2003; Conway Morris, 2006). However, it is still unclear exactly what drove this sudden capacity to construct mineralized structures, be it changes in ocean chemistry (Brennan et al., 2004) or the evolution of more diverse ecologies (Cohen, 2005), including predators (Vermeij, 1989). Investigation of biomineralization processes will provide insight into the molecular and genetic mechanisms that accompanied the appearance of mineralized body parts during the early Cambrian, shedding light on the processes that generate the diversity of life we see around us today.

Until recently, studies of biomineralization processes were mainly restricted to describing the (ultra)structure of the minerals and their interaction with the organic material provided by the organism (Lowenstam and Weiner, 1989; Mann and Webb, 1989). However, the generation and elaboration of biominerals is ultimately controlled by genes (Jackson et al., 2006, 2007a, b), which must in turn be expressed in the appropriate tissue and at an appropriate stage of development. Understanding the evolution of such biomineralizing genes and the gene regulatory networks (GRNs) in which they act is, therefore, vital to the understanding of how animals evolved and will also provide clues for the fabrication of biomimetic materials.

Biomineralization

Biomineralization refers to the processes by which organisms form minerals (e.g., calcium carbonate, calcium phosphate, silica, iron oxides) under strict biological control. These processes are, therefore, defined as *biologically controlled mineralization*, with the skeletons formed being integral, functional parts of the organisms (Lowenstam and Weiner, 1989). There are, however, several other serendipitous processes linked to living organisms (e.g., microbes) or organic substances that result in mineral (mainly calcium carbonate) formation that are not under strict control of organisms. These processes are termed either *biologically induced mineralization*, where inorganic minerals are precipitated by adventitious precipitation resulting from secondary interactions between various metabolic processes and the surrounding environment (Mann, 2001), or *organomineralization*, a term used to describe mineralization processes that involve organic molecules or particles, whether linked to living organisms or not (e.g., degrading organic matter) (Trichet and Defarge, 1995).

While both *biologically induced* and *organomineralization* play an important role in the formation of carbonate systems in the geological record (e.g., microbialites, stromatolites, ooids) (Reitner and Neuweiler, 1995; Arp,

1999; Reitner et al., 2000), it is *biologically controlled mineralization* that is responsible for the production of sophisticated biomaterials such as bones, shells, and teeth, some of which show exceptional strength and beauty, often of high commercial value (i.e., pearls).

Biologically controlled mineralization almost always has organic macromolecules associated with the process of mineral formation, which can comprise up to 5% of the total mass of a biomineral and fulfill important functions during initial crystal nucleation, crystal growth, and growth termination, as well as contributing to the biomechanical properties of the mature product (Simkiss, 1986; Simkiss and Wilbur, 1989). Following the removal of the mineral itself, these organic macromolecules are often subclassified as being either water soluble organic matrices (SOMs), or water insoluble organic matrices (IOMs). IOMs are largely neutrally charged, often highly polymerized, and act as frame building matrices akin to collagen, chitin, or silk proteins (Yan et al., 2007; Yano et al., 2007). SOMs are often highly acidic, due to negatively charged carboxylate groups, are typically rich in aspartic acid (asp) and/or glutamic acid (glu), and usually have mean molecular weight of 10–30 kDa (Bédouet et al., 2001, 2006).

While organic macromolecules appear ubiquitous and pivotal in *biologically controlled* biomineralization (with the focus here on biocalcification), an increasing number of studies now show that a transient amorphous (noncrystalline) phase of calcium carbonate (ACC) is frequently involved in the formation of the earliest stages of calcium carbonate biominerals (Aizenberg et al., 2003; Politi et al., 2004; Weiner and Dove, 2003). However, little is known about the ACC as well as the organic macromolecules involved in calcification in most animal taxa.

Several SOM proteins have been sequenced and characterized, mainly in sea urchins, mollusks, and vertebrates (Treccani et al., 2003; Wilt et al., 2003). About 45 soluble proteins were detected by 2D gel electrophoresis in demineralized spicules from the embryo of the sea urchin *Strongylocentrotus purpuratus* (Killian and Wilt, 1996). Several of these proteins were later cloned and sequenced (e.g., SM27, SM30, SM50) (Zhu et al., 2001) and their role and function in the biomineralization process confirmed by immunohistochemical methods (Ameye et al., 1999; Urry et al., 2000), in situ hybridization (Illies et al., 2002), or by using antisense oligonucleotides directed against spicule matrix proteins (Peled-Kamar et al., 2002). All of the cloned spicule matrix proteins of *Strongylocentrotus* share as common features a C-type lectin domain and proline rich repeat regions. Furthermore, the first 35 amino acids of SpSM32 and SM50 are identical, probably representing splicing variants of the same transcript, although this has yet to be confirmed (Wilt et al., 2003). The precise functions of any of these proteins are unknown (Wilt et al., 2003) and their evolutionary origin and relationships remain largely unresolved (but see Bottjer et al., 2006). An increasing number of reports are, however, elucidating the functional roles of various biomineralizing proteins. For example, the starmaker

protein is known to influence crystal size and lattice formation in otolith biomineralization (Söllner et al., 2003), while the nacre protein perlucin (Mann et al., 2000; Weiss et al., 2000) is known to nucleate the growth of aragonitic calcium carbonate crystals (Blank et al., 2003).

Identification and characterization of the genes directly involved in the process of biocalcification, and the ways in which these “structural genes” are regulated, is essential for our understanding of the evolution of metazoan biocalcification. One of the most advanced systems currently used to study the complexity of the GRNs involved in specifying biomineralizing cell types is the sea urchin. The manipulability of urchin embryos and the availability of a high-quality genome sequence have allowed researchers to identify specific transcription factors (genes that activate the expression of target genes) that activate biomineralizing genes and proteins (Ettensohn et al., 2003, 2007). Furthermore, recent work has identified the nodes in biomineralizing GRNs that are responsible for specifying cells involved in larval skeletogenesis and adult skeletogenesis (Gao and Davidson, 2008), providing insight into the evolution of the metazoan biphasic lifecycle. Such endeavors are also highly relevant to issues of global climate change and ocean acidification – by assessing how resilient marine calcifying organisms are to fluctuations in ocean chemistry, highly species-rich marine ecosystems such as coral reefs may be effectively managed.

The evolution of biocalcification

In the geological record, major animal phyla began biomineralizing shortly before, or during, the so-called Cambrian Explosion, about 530 million years ago, when a highly diverse group of animals appeared suddenly in the fossil record (Knoll, 2003). As most of these phyla are thought to have diverged well before this biomineralization event (Peterson et al., 2008), various causes for this relatively synchronous adoption of biomineralizing strategies have been postulated and remain an area of continuing debate. These include the evolutionary driving force of predation (Vermeij, 1989) or the result of a response to changes in ocean chemistry with greater than previous levels of calcium, requiring the need for effective cellular calcium-detoxification mechanisms (Degens et al., 1985; Kazmierczak et al., 1985).

The vast majority of newly appearing biomineral products in the Cambrian was based on calcium (either as calcium carbonate or calcium phosphate) (Lowenstam and Margulis, 1980). Precise control of intracellular calcium levels is necessary for the formation of microtubules which are needed by eukaryotic cells. Based on this, Lowenstam and Margulis suggested that calcium regulation and transport systems in the late Precambrian metazoans provided the evolutionary prerequisites for their eventual use in biomineralization. CaCO_3 biomineral formation can be useful for the organism because this process allows the elimination of a cell-toxic surplus of Ca^{2+} through enzymes such as calmodulin and membrane

bound Ca^{2+} -ATPase, which directly transports calcium to loci where it is used as a physiological control factor (Degens, 1979).

The question of whether the ability to biocalcify evolved several times independently among various animal groups, possibly to produce armor in response to increased pressure from predators (Marshall, 2006), or whether preexisting calcium regulation and transport systems in the late Precambrian metazoans provided the evolutionary prerequisites for their eventual use in biomineralization (Lowenstam and Margulis, 1980), still remains open to debate. If calcium carbonate biomineralization evolved as a physiological response (mutual to many taxa) to increasing calcium levels in the late Precambrian ocean, then an evolutionary link between the proteins and the regulatory elements involved in skeletogenesis can be postulated among metazoan groups. This evolutionary connection could either be due to massive horizontal gene transfer in ancestral Precambrian organisms or as a result of the exaptation of a preexisting genetic makeup into a new role (biocalcification) in many disparate animal lineages (Kirschvink and Hagadorn, 2000). The latter leads to the hypothesis that the last common ancestor of the metazoa (LCAM) provided a “genetic biomineralization toolkit,” a core set of conserved biomineralization genes to regulate and initiate the cellular functions required for the assembly of calcium carbonate biominerals (Ca^{2+} , HCO_3^-). Subsequently, this core gene cassette and associated regulatory elements have been elaborated upon to produce the range of biomineralized structures we observe in the Earth’s history. One major process by which complex biological systems evolve is by taking an existing genetic pattern evolved for a certain function, duplicating it, and adapting it for a new role (e.g., Carroll et al., 2001). The nascent system is gradually debugged and improved through the process of random mutation and natural selection. This powerful hypothesis, in the context of biomineralization, still awaits an expanded program of comparative geobiological research (Knoll, 2003).

However, evidence for conserved biocalcification mechanisms is beginning to emerge. Some homologies between certain molluscan (Weiss et al., 2001) or sea urchin (Ettensohn et al., 2003) and vertebrate matrix proteins have already been postulated. Ettensohn et al. (2003), for example, found homologies of their sea urchin Sp/LvAlx1 protein, which is an essential component of the gene network that controls downstream genes required for biomineralization, with members of the vertebrate Cart1/Alx3/Alx4 protein family. Members of this gene family have been implicated to be instrumental in the formation of the limb skeleton and the neural crest-derived skeleton of the face and neck in vertebrates. Further, there seems to be some fundamental underlying immunological similarity between macromolecules involved in vertebrate hydroxyapatite and invertebrate aragonite formation (i.e., molluscan nacre), because freshly ground nacre did not result in an immune response when injected into human jaw bones, but in fact

stimulated bone regeneration (Marin and Westbroek, 1998; Lopez et al., 1992). Coral skeletons are already used as bone implants with a similar (albeit weaker) effect on bone regeneration (Demers et al., 2002). Although bone, nacre, and coral skeletons are not homologous structures as such, parts of the complex underlying physiological machinery that controls biomineral formation probably are – a hypothesis strongly supported by the above mentioned results. However, these homologous parts may have served a different function than biomineralization in the (nonskeletonized) common ancestor of corals, mollusks, and vertebrates, later being co-opted for producing biominerals when the necessity arose.

If, as outlined above, calcium carbonate biomineralization systems in the major metazoan phyla evolved from the core skeletogenic toolkit of the last common ancestor of animals, then ancestral metazoan systems should be used as an anchor for a paleogenomic approach to reconstruct this toolkit and explore the evolutionary road map of diversification by comparison with more derived animal taxa. Paleogenomics analyzes the genomes of contemporary taxa to reconstruct ancient genomes and genomic features and to infer the function of ancestral genes.

Recent paleogenomic studies go beyond the focus on classical matrix proteins. Expressed sequence tags (ESTs), cDNA libraries, and recently sequenced genomes have been utilized to examine the inheritance of ancestral toolkits that were involved in skeletogenesis. By using a calcifying coralline sponge of a “living fossil,” *Astrosclera willeyana*, a key component of the ancestral skeletogenic toolkit – α -carbonic anhydrase – has been identified (Jackson et al., 2007b). Duplication of this gene is likely to have allowed biocalcification to evolve in many clades of metazoans. In contrast, the recently sequenced genome of the sea urchin *Strongylocentrotus purpuratus* has revealed that genes essential for the construction of the echinoderm skeleton (the stereome) are echinoderm-specific and are likely to be the same as those in the earliest echinoderms and their direct ancestors more than 520 million years ago (Livingston et al., 2006). Similarly, in gastropods (snails; *Haliotis asinina* and *Lottia scutum*) an unexpected level of genetic novelty and complexity in the skeletogenic toolkit suggests that there are significant molecular differences in the ways in which gastropods synthesize their shells (Jackson et al., 2006). These features, along with the modular design of the molluscan mantle, contribute to the spectacular morphological and mineralogical variety we observe among contemporary mollusk shells (Jackson et al., 2007a).

From the limited data available, we can develop the following scenario as a working hypothesis (Figure 1): the last LCAM possessed a core biomineralization toolkit that at least consisted of an α -carbonic anhydrase, providing the core capacity to regulate the reversible hydration of CO_2 , necessary for biocalcification. Other, as yet undiscovered, parts of this toolkit most likely contained genes that regulate Ca^{2+} trafficking, scaffolding genes for organic matrix production, as well as regulatory

Animal Biocalcification, Evolution, Figure 1 Conceptual summary. The last common ancestor of all Metazoa (LCAM) possessed a core gene toolkit for the regulation of Ca_2^+ and an alpha-carbonic anhydrase to catalyse the reversible hydration of CO_2 . During subsequent metazoan evolution, parts of this toolkit (genes and regulatory elements) were exapted to new roles including calcium carbonate fabrication. Novel genes and biosynthetic pathways were added to the conserved biocalcification toolkit to produce the variety of skeletal forms we observe among extant animal lineages.

elements. During subsequent animal evolution, genes in this core set were duplicated in different lineages, resulting in a relatively simple genetic repertoire in basal metazoans, but in a highly diverse gene array in the various lineages of the Bilateria (Ecdysozoa, Lophotrochozoa, and Deuterostomia). A high degree of lineage-specific innovation on top of a conserved gene-set then allowed for the diversification of the numerous skeletal architectures we observe since the dawn of the Cambrian.

Conclusion

While the structural processes of biomineralization, and in particular biocalcification, are receiving vigorous attention from various international groups, a far more detailed characterization of the core ancestral skeletogenic toolkit as well as lineage specific innovations are needed before we understand how the impressive diversity and beauty of metazoan skeletal structures originated and evolved. As this knowledge is acquired, we can anticipate the construction of new high-performance biomimetic materials and the measurement and prediction of the resilience of marine calcifying organisms to rapidly changing environmental parameters, such as ocean acidification.

Early biomineralization event; Small shelly fossils

Definition

Animal skeleton. Biologically, an animal skeleton is a hard or rigid framework that could provide protection and

support in many types of animals. Most of the animal skeletons are mineralized, but some of them may not be mineralized (e.g., some annelid tubes being agglutinated). They could be subdivided into exoskeletons and endoskeletons, excluding hydroskeletons. The “skeletons” of resistant organic biopolymers are not included herein.

Exoskeleton. Exoskeletons are external hard parts. They may enclose the soft tissues and organs of the body, or may be external sclerites.

Endoskeleton. Endoskeletons are internal hard parts (typical of many vertebrates). Most of the endoskeletons are generally surrounded by skin and musculature.

Small shelly fossils (SSF or SSFs). A non-taxonomic term was first used by Matthews and Missarzhevsky in the title of their review paper in 1975 to denote the earliest skeletal fossils, although some of these fossils may not be small and most of them are actually not shells. It has been popularly used in literature somewhat as a catchall term for the early Cambrian skeletal fossils, including spicules, shells, tubes, and diverse disarticulated sclerites.

Introduction

Skeletal biomineralization (skeletonization) was part of the initial diversification of early animals. The fossil record provides an important clue to the origin of biomineralization in the animal phyla (Kirschvink and Hagadorn, 2000). The earliest occurrence of animal skeletons was in the late Ediacaran, e.g., *Cloudina*, *Sinotubulites*, and *Namapoikia*, although the generic diversity was quite low and the biomineralization of these calcareous skeletons was not well controlled biologically (Grant, 1990). The early Cambrian (542–525 Ma) saw the largest burst of diversified animal skeletons, represented in the fossil record by poriferans, cnidarians, many extant bilaterian phyla, and some problematic taxa (Figure 1) (Bengtson, 2004). In terms of structural and mineralogical diversity of animal skeletons, the early Cambrian represents a quantum jump (Bengtson and Conway Morris, 1992). The abrupt advent of diversified skeletal fossils not only has been taken as a major piece of evidence for the Cambrian radiation but also was envisioned the biomineralization event. Since most of these skeletal fossils are typically small in size, and lots of them represent disarticulated sclerites and are enigmatic with respect to their biological affinities, they are commonly referred to as “small shelly fossils (SSFs)” in the literature (Matthews and Missarzhevsky, 1975; Qian, 1999). But some of the early skeletal fossils, such as the sponge-like archaeocyaths, trilobites, and bivalved arthropods, are rarely described under this nontaxonomic term, while some fossils described under the term of SSFs, such as embryo fossils and cnidarian polyps, may have been originally composed of resistant organic membranes or tubes without biomineralization, and the skeleton-like appearance is mainly due to the secondary phosphatization.

Animal Skeletons, Advent, Figure 1 Distribution of major skeletal animal taxa (biomineralized and agglutinated) from the late Ediacaran to the early Cambrian.

Mineralogy of early animal skeletons

Animals use a variety of minerals to fabricate their skeletons (Lowenstam and Weiner, 1989). However, there are only three principal classes of minerals being widely used by organisms, including calcium carbonates, calcium phosphates, and silica. Calcium, carbonate, and phosphate ions are abundant in the oceans, and are ready for use in skeletons (Kirschvink and Hagadorn, 2000), despite

skeletogenesis being a biologically controlled, complex process. Animals rarely switched their mineralogy after their first skeletogenesis, indicating that, for most lineages, environment does not strongly influence skeleton composition, although the selection of skeletal mineralogy during the first acquisition of skeletons in a clade may be somewhat related to ambient seawater chemistry (Knoll, 2003; Porter, 2007; Zhuravlev and Wood, 2008).

It is in most cases not apparent to identify the original minerals of early fossil skeletons because of diagenetic alterations. Especially, there was a very significant phosphogenic event around the Ediacaran-Cambrian transition (Cook and Shergold, 1984), and thus secondary phosphatization of early skeletal fossils was quite common (Qian and Bengtson, 1989). The original composition of fossil skeletons can be learnt by inference and comparative analysis. The fossil record shows that early animals mainly used calcium carbonates, apatites, and silica to build their skeletons (Figure 1).

Several polymorphs of calcium carbonates are the major skeleton-forming minerals, including calcite (high-Mg calcite, low-Mg calcite), aragonite, and vaterite. Vaterite is an extremely unstable polymorph of CaCO_3 and is rarely used as a biomineral. Aragonite is an unstable mineral and it is easily transformed to low-Mg calcite during diagenesis; hence, the original mineralogy of early calcareous fossils is difficult to identify in many cases (Bengtson and Conway Morris, 1992). The earliest animal skeletons during the late Ediacaran-Tommotian interval were composed exclusively of aragonite and high-Mg calcite, being consistent with an aragonite sea (Porter, 2007; Zhuravlev and Wood, 2008). Since the early Atdabanian, there occurred many clades of animals using low-Mg calcite to make skeletons, implying the onset of a calcite sea.

Apatite is another major mineral for early animals to make skeletons (Figure 1), and it is diagenetically the most stable among the major skeleton-building minerals (Bengtson and Conway Morris, 1992). Phosphatic skeletons are usually a combination of phosphate and organic material and hence are called organo-phosphatic. Comparative study indicates that phosphatic skeletons in the

earliest metazoans appear to have been more widespread than today (Runnegar and Bengtson, 1990). The early phosphatic skeletal metazoans include brachiopods (Linguliformea), cnidarians (hyolithelminths, byroniids, and conulariids), bradoriids, lobopodian, protoconodonts, and conodont-like fossils, tomotiids, etc. The high diversity of phosphatic skeletons is somewhat related to wide distribution of phosphate deposits (phosphogenesis event) in various parts of the world during the early Cambrian (Cook and Shergold, 1984).

Siliceous (opal) skeletons differ in distribution from those made of CaCO_3 since silica biomineralization is limited to intracellular precipitation. Therefore, in animals, siliceous skeletons are limited to sponge spicules and other minor occurrences (Bengtson and Conway Morris, 1992). Opal has been used by sponges (including Demospongea and Hexactinellida) to build their skeletons since the late Ediacaran (Gehling and Rigby, 1996). Biogenic opal is unstable and it usually recrystallizes to quartz during diagenesis.

Agglutinated conchs are occasionally found in the Lower Cambrian rocks such as *Salterella*, *Volborthella*, and *Platysolenites*. Both *Salterella* and *Volborthella* are metazoans (Yochelson and Kisselev, 2003), but their biological affinities are uncertain. They have a calcareous sheath partially filled with detrital grains, agglutinating into laminations. *Platysolenites* represents an agglutinating foraminiferan (Glaessner, 1963).

Morphological variety of early animal skeletons

The morpho-types of the animal skeletons in the late Ediacaran are relatively few. They are mainly represented by weakly mineralized calcareous tubes (e.g., *Cloudina*,

Animal Skeletons, Advent, Figure 2 Examples of late Ediacaran skeletal fossils. (j1, j2) *Tannuolina*, mitral and sellate sclerites (tommotiids); (k) *Lapworthella*, a sclerite (tommotiids). All from the Lower Cambrian of South China. (d–f2: After Qian and Bengtson, 1989). Scale bars = 100 μm , except in j2 = 500 μm .

Sinotubulites) (Figure 2) (Hua et al., 2005), modular skeletons (e.g., *Namapoikia*) (Wood et al., 2002), sponge spicules (Brasier et al., 1997) or a reticulating net of spicules (e.g., *Paleophragmodictya*) (Gehling and Rigby, 1996), and goblet-shaped *Namacalathus* (Grotzinger et al., 2000).

Various types of the animal skeletons abruptly occurred in the early Cambrian. Using the theoretical “Skeleton Space” concept, Thomas et al. (2000) made an analysis of Cambrian animal skeletons. Their analysis showed that about 50% of skeletal design elements recognized among living and extinct marine metazoans were exploited in the early Cambrian (Tommotian) and about 80% exploited in the middle Cambrian Burgess Shale animals. The early Cambrian animal skeletons include univalved (Figure 4d, i, n) and bivalved shells (Figure 4e, f), arthropod carapaces (Figure 4g, h), diverse tubes (Figure 4a–c, l), spicules, diverse external sclerites (Figure 3), tooth-like structures (Figure 3c–e), calcareous massive reinforcements (e.g., archeocyathans), echinoderm ossicles, etc.

Late Ediacaran skeletal metazoans

Prior to the Cambrian, the evidence for animal life was almost the soft-bodied Ediacaran fauna and the advent of skeletal animals had been considered to be in the lowermost Cambrian until Germs (1972) described the first Precambrian skeletal fossil *Cloudina* from the Nama Group in Namibia. Since then, biomineralized fossil assemblages have been widely found in the latest Ediacaran over the world, although the biodiversity is very low. Up to now, there are only several skeletal fossil genera being discovered from the Upper Ediacaran rocks, including *Cloudina*, *Sinotubulites*, *Namapoikia*, *Namacalathus*, and *Paleophragmodictya*. Most genera became extinct at the base of the Cambrian, suggesting that a mass extinction occurred at the latest Ediacaran (Amthor et al., 2003).

The worldwide distributed *Cloudina* is a calcareous conical fossil consisting of funnel-like, apically flaring cones nested with one another (Figure 2a, b). The zoological affinities of *Cloudina* are uncertain, but occasional evidence for budding supports either a cnidarian interpretation

Animal Skeletons, Advent, Figure 4 Examples of early Cambrian tube-dwelling and shell-bearing animals. (a) *Torellella*, a tube-like fossil of unknown affinity; (b) *Anabarites*, a tube-like fossil of cnidarian. (c) *Conotheca*, a hyolith; (d) *Aldanella*, a possible gastropod; (e) A ventral valve of *Eohardrotreta*, acrotretid brachiopods; (f) A ventral valve of *Palaeobolus*, lingulid brachiopods; (g) *Dabashanella*, a phosphatocopid; (h) *Kunmingella*, a bradoriid; (i) *Canopoconus*, a possible mollusk; (j) *Hexangulaconularia*, a conulariid (Cnidaria); (k) *Lathamella*, a stem-group brachiopod; (l) *Cupitthea*, a tube-like fossil of unknown affinity; (m) *Watsonella*, a rostroconch (Mollusca); (n) *Archaeospira*, a gastropod. All from the Lower Cambrian of South China (b, c, i, n: After Qian and Bengtson, 1989). Scale bars = 100 μ m.

(Grant, 1990) or an annelid relation (Hua et al., 2005). The *Cloudina* tubes contain the earliest evidence of predatorial borings (Figure 2b). The enigmatic *Sinotubulites* (Figure 2c, d) is a cylindrical fossil, and its tube is composed of several thin layers and characterized by “tube-in-tube” structure (Chen et al., 2007). It has been only documented from the Dengying Formation in South China and co-occurred with *Cloudina*. The irregular wrinkle ornamentation of outer layer shows the *Sinotubulites* tubes being plastic, implying that the tube wall was dominantly organic with aragonitic mineralization (Chen et al., 2007).

Namapoikia is a late Ediacaran, fully biomineralized metazoan from the Nama Group, Namibia, and it is up to 1 m in diameter and bears a complex and robust calcareous skeleton (Wood et al., 2002). It resembles chaetid sponges or simple colonial cnidarians. *Namacalathus* is another calcified animal from the late Ediacaran, and it is goblet shaped up to 2 cm across (Grotzinger et al., 2000). It is more likely to be a cnidarian than a sponge. Both *Namapoikia* and *Namacalathus* co-occur with *Cloudina*.

Hexactinellid sponges have also been found in the late Ediacaran, including the body fossil *Paleophragmodictya*

(with a reticulating net of spicules) (Gehling and Rigby, 1996) as well as clusters of siliceous spicules (Brasier et al., 1997).

Early Cambrian skeletal metazoans

The great watershed in skeletal biomineralization was the early Cambrian, where the diversity of skeletal animals increases nearly exponentially over the interval. Compared with the limited diversity of skeletal fossils in the Ediacaran, the Lower Cambrian is marked by an extraordinary burst of skeletal fossils. Most skeletal metazoans (extant and extinct) appeared for the first time during the early Cambrian (Figure 1). Among these skeletal fossils, many “skeletons” were not integrated and consisted of numerous discrete sclerites, e.g., cambroclaves, tomotiids, halkieriids, cancelloriids, etc. (Figure 3).

Although the advent of animal skeletons in the early Cambrian is quite abrupt or explosive in relation to the long geologic history, the first appearances of different clades in the early Cambrian are sequential (Li et al., 2007). Anabaritids, hyoliths, maikhanellids (mollusks),

and protoconodonts (chaetognaths) first occurred in the early Meishucunian, coeloscleritophorans, tommotiids in the middle Meishucunian, while crown group brachiopods, skeletal arthropods, and lobopods first occurred in the early Qiongzhusian (Figure 1). The skeletal fossil record shows that the clades occurring in the pre-trilobitic interval (Meishucunian) include many extant phyla such as Porifera, Cnidaria, Annelida, Mollusca, Chaetognatha, Brachiopoda (Lingulids), and a number of extinct taxa such as Hyolitha, stem-group brachiopods, tommotiids, coeloscleritophorans, cambroclaves, coleoloids, paracarinachitids, etc. The pre-trilobitic skeletal fossils were dominated by helcionellids (Mollusca), hyoliths, other problematic sclerites, cap-shaped fossils, and tube-like fossils. They are distinctively different from the “Cambrian Evolutionary Fauna,” and were christened the “Tommotian Fauna” (Sepkoski, 1992).

In the Qiongzhusian (Atdabanian) stage, besides many extinct clades, nearly all extant skeletal invertebrate phyla occurred (except Byrozozoa with first occurrence in the early Ordovician). The dominant and characteristic skeletal fossils of this interval include arthropods, brachiopods, and echinoderms, representing an initial stage of the “Cambrian Evolutionary Fauna.”

Summary

The earliest skeletal fossils came from the late Ediacaran rocks, but the early Cambrian witnessed the largest burst of animal skeletons. The abrupt advent of diverse skeletal fossils is an important part of the Cambrian explosion, and biomineralization of animal hard parts provides many advantages for metazoan diversification. Although the trigger for this early biomineralization event has been a subject of extensive debate in literature, it should be an integrating result of extrinsic and intrinsic (biological) factors. The fossil record also exhibits that, along with the rapid diversification of metazoans in the early Cambrian, the metazoans progressively exploited more ecological space. Most of the pre-trilobitic skeletal faunas came from the shallow-water deposits, but during the Qiongzhusian, there already existed a distinct differentiation of shallow water and deep water habitats: a strong linkage between the occurrences of the skeletal fossils and sedimentary environments.

 University of Göttingen, Göttingen, Germany

Synonyms

Archaeobacteria (term abandoned)

Definition

The Archaea are single-celled or filamentous prokaryotes that constitute the third phylogenetic domain of life, besides the Bacteria and the Eukarya. The word “Archaea” (singular archaeum, archaeon) is derived from the Greek word for “the old ones”.

History

The discovery of the Archaea dates back to 1976 when Carl Woese, at his laboratory at Illinois University, compared prokaryotic small subunit ribosomal RNA sequences using oligonucleotide catalogs (Woese, 2007). Woese recognized *Methanobacterium thermoautotrophicum* as the first member of a fundamentally distinct group of prokaryotes that clustered away from all other bacteria. Consequently, Woese and Fox (1977) established the concept of two separate prokaryotic “urkingdoms,” Eubacteria and Archaeobacteria. Later, the term “Archaeobacteria” was changed to “Archaea” to emphasize the fundamental differences between both groups. Based on these discoveries, Woese and his coworkers proposed the now-accepted division of life into the three domains of Archaea, Bacteria, and Eukarya (Figure 1; Woese et al., 1990).

Specific traits

Like the Bacteria, most Archaea show a cell size between 0.5 and 2 μm and lack a cell nucleus, internal membranes, and organelles. However, a number of traits distinguish the Archaea from members of the other domains of life:

1. The genetic machinery of Archaea is different from Bacteria and Eukarya. The distinctive archaeal “signature” contains more than 1,000 archaeal protein-encoding genes. These signature genes account for a significant portion (9–15%) of archaeal genomic DNA (Graham et al., 2000). The archaeal RNA polymerase, an enzyme producing RNA chains from DNA gene templates, consists of eight (methanogens

Archaea, Figure 1 The phylogenetic tree of life. (Redrawn after Madigan and Martinko, 2006.)

- and halophiles) or ten (hyperthermophiles) individual polypeptides. These polymerases are quite different from those of the Bacteria (four polypeptides), but somewhat similar to those of the Eukarya (10–12 polypeptides; Madigan and Martinko, 2006).
2. Unlike bacteria, the cell walls of the Archaea contain no peptidoglycan (a polymer consisting of sugars and amino acids, also known as murein). Rather, archaeal cell walls exhibit a variety of compositions (Kandler and König, 1998). They may consist of the murein analog pseudomurein, polysaccharides, proteins, or glycoproteins (Madigan and Martinko, 2006).
 3. Archaea possess glycerol-based phospholipids as building blocks of their cell membranes, as do bacteria and eukaryotes. However, some features of the archaeal membrane lipids set them apart, namely (a) the stereochemistry of the glycerol moiety (L instead of R), (b) the linkage between the alkyl chains and the glycerol molecules (ether instead of ester bonds), and (c) the design of the alkyl chains (isoprene-based instead of acyl-based; DeRosa and Gambacorta, 1988). In many archaea, these chains are long enough (C₄₀) to span the whole membrane, forming a monolayer instead of the lipid bilayer typical for other organisms (Koga et al., 1993). These isoprenoid lipids, or degradation products thereof, are excellent tracers for archaea-derived organic matter inputs and biogeochemical processes in modern and ancient sediments (Hopmans et al., 2000; Kuypers et al., 2001; Peckmann and Thiel, 2004; see entry *Biomarkers*).

Phylogeny

Most Archaea, and all cultured species, belong to two major, well-established subdivisions, the Euryarchaeota, which include methanogens and extreme halophiles, and the Crenarchaeota, which encompass predominantly hyperthermophiles and anaerobic respirers (Figure 1). Further lineages, namely Korarchaeota (Barns et al., 1996), Nanoarchaeota (Huber and Rachel, 2007), and the Ancient Archaeal Group (Takai and Horikoshi, 1999), have been proposed based on 16S rDNA amplification from environmental samples and/or co-cultivation in mixed laboratory enrichments (Gribaldo and Brochier-Armanet, 2006; Schleper, 2007). However, most of these newly proposed groups still await detailed characterization.

It is as yet unclear at which time in Earth history the domain Archaea arose (Gribaldo and Brochier-Armanet, 2006). Isotopic signatures indicate the presence of methane-cycling archaea 2.8–2.6 billion years ago. Other molecular estimates placed the divergence between Euryarchaeota and Crenarchaeota even 4.1 billion years ago, but this was inferred by using the plant/animal divergence as a calibration point (Battistuzzi et al., 2004). Unequivocal archaeal biosignatures in Precambrian rocks are therefore urgently needed to provide reliable calibration

points for the molecular dating of Archaea and prokaryotes in general (Gribaldo and Brochier-Armanet, 2006).

Ecology

Until recently, it had been thought that archaea are largely restricted to particular ecological niches. Indeed, many archaea are extremophiles (see entry *Extreme Environments*), with growth optima at the most extreme pH values, ranging from pH 1 (*Sulfolobus acidocaldarius*) to pH 12 (*Natronococcus*). Moreover, numerous species are hyperthermophiles, with growth optima above 80°C. The current record for growth temperatures (122°C) is held by a methanogen, *Methanopyrus kandleri* (Takai et al., 2008). Likewise, many halophilic archaea can tolerate extremely high salt concentrations, even at the saturation limit for NaCl (5.5 M; Barns and Nierzwicki-Bauer, 1997; see entry *Halobacteria – Halophiles*). However, ongoing research employing culture-independent molecular techniques and biomarker studies revealed that archaea are by no means restricted to extreme environments. Rather, they are globally distributed and occur in virtually all “normal” settings as well, including soils and freshwater environments (Schleper, 2007), marine planktonic communities (>20% of the total rRNA, >14% of the total cell counts in sea water; Giovannoni and Rappé, 2000), and marine sediments (Lipp et al., 2008). Archaea are also found as partners in symbioses, e.g., with other archaea (Huber and Rachel, 2007), bacteria (Boetius et al., 2000; Stams and Plugge, 2009), ciliates (van Hoek et al., 2000), sponges (Margot et al., 2002), ruminants (Wright et al., 2006), and even in human intestines (Eckburg et al., 2005; see entry *Symbiosis*).

Metabolism

Some examples for biochemical pathways used by the Archaea are given in Table 1.

The Archaea exhibit a wide range of metabolic capacities, however, all members are chemotrophic. Phototrophy, in a strict sense, does not occur among the Archaea, although some halophilic archaea produce pigments, bacteriorhodopsin-like, light driven proton, or ion pumps that allow them to utilize sunlight for biosynthesis, but in a way very different from phototrophic organisms (Madigan and Martinko, 2006). *Chemoheterotrophic* archaea utilize organic substances, particularly metabolic products of other microbes formed during organic matter degradation (Barns and Nierzwicki-Bauer, 1997). These substrates usually consist of simple C₁ and C₂ compounds, such as methanol or acetic acid. Methane and CO₂ are typical metabolic products of archaeal chemoheterotrophy. *Chemolithotrophic* archaea fix inorganic carbon, with hydrogen gas derived from geochemical processes or microbial metabolism being widely used as an energy source (Pedersen, 1997; Berg et al., 2010).

Some archaea perform iron reduction using Fe(III) as an electron acceptor and hydrogen gas or organic compounds as an electron donor (Bond and Lovley, 2002;

Archaea, Table 1 Some examples for biochemical pathways used by archaea

Reaction	
$2\text{H}_2 + \text{O}_2 \rightarrow 2\text{H}_2\text{O}$	Hydrogen oxidation
$\text{H}_2 + \text{S}^0 \rightarrow \text{H}_2\text{S}$	Sulfur reduction
$4\text{H}_2\text{S} + 2\text{O}_2 \rightarrow 4\text{H}_2\text{SO}_4$	Sulfide oxidation
$2\text{S}^0 + 3\text{O}_2 + 2\text{H}_2\text{O} \rightarrow 2\text{H}_2\text{SO}_4$	Sulfur oxidation
$\text{H}_2 + \text{NO}_3^- \rightarrow \text{NO}_2^- + \text{H}_2\text{O}$	Nitrate reduction
$\text{H}_2 + 2\text{Fe}^{3+} \rightarrow 2\text{Fe}^{2+} + 2\text{H}^+$	Iron reduction
$\text{CO}_2 + 4\text{H}_2 \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$	Methanogenesis (autotrophic)
$4\text{CH}_3\text{OH} \rightarrow 3\text{CH}_4 + \text{CO}_2 + \text{H}_2\text{O}$	Methanogenesis (heterotrophic)
$4\text{CH}_3\text{COO}^- + \text{H}_2\text{O} \rightarrow 3\text{CH}_4 + \text{HCO}_3^-$	Methanogenesis ("acetoclastic," heterotrophic)
Organic compound + $\text{O}_2 \rightarrow 2\text{H}_2\text{O} + \text{CO}_2$	Aerobic respiration

Kashefi et al., 2002; see entry *Fe(III)-Reducing Prokaryotes*). Other members of the Archaea drive pathways of the nitrogen cycle, such as ammonia oxidation, nitrate respiration and denitrification, and assimilatory pathways like N_2 fixation and nitrate assimilation (Cabello et al., 2004; see entry *Nitrogen*). In addition, sulfur is a central component for reactions performed by numerous thermophilic archaea. Elemental sulfur (S^0), thiosulfate ($\text{S}_2\text{O}_3^{2-}$), sulfite (SO_3^-), or sulfate (SO_4^{2-}) may be used as electron acceptors, and elemental sulfur (S^0) or H_2S as electron donors, depending on species and environmental conditions (Barns and Nierzwicki-Bauer, 1997, see entry *Sulfur Cycle*).

Methanogenic archaea (methanogens) are anaerobic euryarchaeotes that produce methane as a metabolic end product of various reactions (Table 1, see entry *Methane, Origin* for details). For several reasons, these archaea are of particularly interest from a geobiological perspective. (a) Chemoorganotrophic methanogens thriving on simple metabolic products of other (micro)organisms such as methanol or acetate (acetoclastic methanogenesis, Table 1) are key players in the degradation of organic matter in sediments (see entry *Carbon (Organic, Degradation)*). (b) Chemolithotrophic methanogens, utilizing only hydrogen gas and CO_2 may thrive in dark and extremely organic-lean environments. (c) Many methanogens are thermophiles (growth temperatures $>60^\circ\text{C}$) or hyperthermophiles (growth temperatures $>80^\circ\text{C}$) with some species being even capable of withstanding temperatures above 100°C (Huber et al., 1990; see entry *Extreme Environments*). Archaea are therefore predestined to pioneering life in extreme settings such as the Deep Biosphere (Hallbeck and Pedersen, 2008), Hot Springs, and Hydrothermal Environments (see these entries). Third, the product of archaeal methanogenesis, "biogenic" methane, may accumulate in sedimentary reservoirs either as free natural gas or, under certain low-temperature/high-pressure conditions, frozen as solid gas hydrates (see entry *Cold Seeps*). Sedimentary methane reservoirs play a crucial role as an energy resource for man, but when released into the atmosphere, methane may act as a strong driving force of global change (Mascarelli, 2009). In as much as methane is an effective

Archaea, Figure 2 Cylindrical cells of archaea belonging to the ANME-1 group of methanotrophic archaea. Individual cells are about $0.5\ \mu\text{m}$ in diameter. (Image courtesy of J. Reitner.)

greenhouse gas being more than 20 times as potent as CO_2 per molecule, it presently contributes more than 20% to the current global greenhouse effect (IPCC, 2007). Several dramatic events in Earth history, such as the Paleocene/Eocene thermal maximum, have been attributed to sudden increases of atmospheric methane concentrations, possibly induced by rapid methane release due to gas hydrate dissolution (Zachos et al., 2008).

Methanotrophic archaea (ANME, *anaerobic methane oxidizers*, Figure 2), organisms that reversed the methanogenic metabolism, have recently been specified as members of sedimentary microbial communities in anoxic sediments. Living together in a syntrophic consortium with sulfate reducing bacteria, ANME oxidize methane by sulfate or nitrate (Raghoebarsing et al., 2006; Knittel and Boetius, 2009; see entry *Anaerobic Oxidation of Methane with Sulfate*).

Biom mineralization

In methane-rich environments, ANME are key players in the formation of calcium carbonate (CaCO_3) deposits, the so-called seep carbonates or methane-derived

Archaea, Figure 3 A Miocene (~16–20 million years old) carbonate deposit that formed as a result of archaeal methanotrophy (Terzi et al., 1994). Croce della Moggiona, Lower Vicchio Formation, Tuscan Apennines, Italy. (Image courtesy of J. Peckmann.)

carbonates (Figure 3; Peckmann and Thiel, 2004; Reitner et al., 2005; see entry *Cold Seeps*). This biologically induced mineralization process is driven by an increase in *Alkalinity* resulting from the anaerobic oxidation of methane. The anaerobic oxidation of methane may also be involved in dolomite ($\text{Ca, Mg}(\text{CO}_3)_2$) precipitation in marine sediments (Moore et al., 2004). Likewise, methanogens have been linked to dolomite formation in shallow groundwater aquifers (Roberts et al., 2004). Recent laboratory experiments identified acetoclastic and autotrophic methanogenesis associated with dolomite formation (Kenward et al., 2009; see entry *Dolomite, Microbial*).

Summary

The Archaea are a group of unicellular prokaryotes representing the third domain of life, in addition to Bacteria and Eukarya. The Archaea differ from the latter by aspects of their genomic machinery, cell wall composition, and membrane lipid structure. Although the timing of their emergence has not been determined, it is believed that the Archaea have been key players within the carbon, nitrogen, and sulfur cycles for the major part of Earth history. Regarding their ecophysiology, individual archaeal groups display unique capacities, such as methanogenesis,

extreme salt tolerance, and survival at temperatures even higher than 100°C. However, environmental surveys revealed the Archaea to be abundant and metabolically versatile not only in extreme environments, but also in “normal” habitats such as soil, oceans, and freshwater. Archaea involved in methane cycling have also been identified as drivers of biologically induced mineralization resulting in (carbonate) rock formation.

Definition

Arsenic, element 33, is a metalloid in row VB of the periodic table. The main oxidation states are arsine (−3) elemental As(0), arsenite (+3), and arsenate (+5). Arsenate, As(V), and arsenite, As(III), are most common, with HAsO_4^{2-} and $\text{H}_2\text{AsO}_4^{1-}$ predominating under oxic conditions and H_3AsO^0 and $\text{H}_2\text{AsO}_3^{2-}$ prevalent in anoxic environments. Arsenic is found in minerals such as arsenosulfides (e.g., arsenopyrite, realgar), iron hydroxides and aluminosilicates (e.g., clays), fossil fuels, geothermal sources, and weathered volcanic and evaporitic deposits. Anthropogenic inputs may also be considerable as organoarsenicals such as roxarsone (3-nitro-4-hydroxy benzene arsonic acid) and monosodium and disodium methyl arsonate continue to see wide spread use. The toxicology of arsenic is well known; As(V) is an analog of phosphate and can disrupt oxidative phosphorylation, while As(III) binds to sulfhydryl groups and can inhibit respiratory enzymes. Nevertheless, arsenic is readily metabolized by microorganisms, undergoing redox reactions involved in resistance or energy generation. Organarsenicals are used for energy generation or as a carbon source. Environments with elevated concentrations can support a diverse arsenic metabolizing microbial community and a robust biogeochemical cycle (Oremland and Stolz, 2003).

As(III)-oxidizing prokaryotes are found among the alpha-, beta-, and gamma-proteobacteria, Deinocci (i.e., *Thermus*), and Crenarchaeota. Physiologically diverse, they include heterotrophic and chemolithoautotrophic species. The oxidation of arsenite involves the arsenite oxidase (AoxAB or AroBA), a member of the molybdenum family of enzymes. The gene sequence of the catalytic subunit (*aoxB* or *aroA*) is highly conserved, and oligonucleotide primers have been used to investigate the occurrence and distribution of As(III)-oxidizing

species. The dissimilatory reduction of As(V) has been demonstrated in Crenarchaeota, thermophilic bacteria, gamma-, delta-, and epsilon-proteobacteria, and low and high mole %GC gram positive bacteria. The enzyme, ArrAB, is also a molybdoenzyme, but differs significantly from AoxBA. The *arrA* gene has also been used as an environmental probe. Arsenic resistance involves a completely different type of arsenate reductase (ArsC, ACR2). Three different but comparable resistance systems (e.g., *E. coli*, *Staphylococcus*, *Saccharomyces*) have been described. ArsC catalyzes the reduction of arsenate to arsenite, while an arsenite-specific efflux pump (ArsB, ACR3) expels As(III) from the cell. Additional components include an ATPase (ArsA) and regulatory elements (ArsR, ArsD). Far less is known about arsenic methylation and demethylation, however, a SAM-dependent methylase has recently been described (Stolz et al., 2006).

Different microbially mediated processes can result in arsenic contaminated aquifers including (1) the oxidation of arsenic-containing pyrites, (2) the release of As(V) from reduction of iron oxides by autochthonous organic matter, (3) the reduction of iron oxides by allochthonous organic matter from dissolved organics in recharging waters, (4) the exchange of adsorbed As(V) with fertilizer phosphates, and (5) recharge with water contaminated with inorganic arsenic derived from the application or production of wood preservatives, pesticides (e.g., calcium arsenate), and organoarsenicals (e.g., roxarsone). Thus organisms that metabolize arsenic can impact the speciation, mobility, and toxicity of arsenic in the environment (Oremland and Stolz, 2005).

ASTEROID AND COMET IMPACTS

Charles S. Cockell
 Open University, Milton Keynes, UK

Definition

The impact of an extraterrestrial object (either an asteroid or comet) with the Earth's surface.

Introduction

There are now over 170 asteroid and comet impact craters that have been identified on the surface of the Earth (Table 1). These craters represent a small subset of the total impacts that have occurred during the history of life. Today, impact craters probably represent something on the order of 50,000 km² of Earth's surface. Although this is a small habitat area, impacts are the only extraterrestrial mechanism capable of causing localized ecological disturbance. Because impacts are a mechanism capable of delivering a pulse of energy into ecosystems, from a geobiological point of view they present an important addition to the overall picture of how ecosystems are disturbed and how they recover through time. Comparison to other processes involving ecological disturbance and recovery including volcanism, glaciation/deglaciation, storm damage, fire, landslides, and coastal erosion allows for a more complete picture of the role of catastrophic change in shaping the geobiology of the Earth.

Effects of impacts on the local environment

The kinetic energy associated with the collision of an asteroid or comet with the Earth is enormous. The collision of a rock with a 10-km diameter could release the equivalent energy of 10 million tonnes of TNT. An event on such a scale is expected to occur, on average, once in every 100 million years, and may be capable of causing global-scale disruption and extinction. Such an event is implicated in the Cretaceous–Paleogene extinctions. It is perhaps not surprising, therefore, that the biological destructiveness of impact events has overwhelmingly influenced our view of these objects and their role in ecological and evolutionary processes. However, it is important to realize that the great majority of impacts only cause effects at the local scale, although they may distribute material from the point of impact over wide areas. This contribution will focus on the local geobiological effects of impacts.

The impact of an asteroid and comet with the surface of the Earth has two profound effects that are relevant for life. First, the impact delivers energy into the target area with important geological consequences and second, it rearranges the hydrologic cycle, with implications for the availability of liquid water. Temperatures generated in

the impact cratering process can exceed several thousand degrees centigrade (Melosh, 1989). Most biologically important macronutrients volatilize at temperatures much lower than those associated with temperatures generated in the crater during impact (e.g., nitrates, 200°C; organic phosphorus, 350°C; inorganic phosphorus, 750°C; sulphur, 450°C; potassium, 570°C; and sodium, 880°C). In some parts of the crater, the substrate will not only be sterilized (made devoid of life), but will also be rendered oligotrophic (i.e., lacking in nutrients). The process and/or the extent of recolonization on melted and shocked substrates might be very different to that taking place on unprocessed substrate either inside or outside the crater and it might be very different from that associated with other agents of local ecological disturbance.

Recovery from impacts

Following the impact, there will be a well-defined sequence of biological recovery within the crater (Cockell and Lee, 2002). As there has been no large scale impact event in recorded human history, there has been no opportunity to observe these changes directly unlike post-volcanic recovery. However, observations on the present-day colonization of impact craters, which are in various states of preservation, can yield insights into the likely sequence of events (Cockell and Lee, 2002) and particularly the long-term influence of impacts on the geobiology of a region. Some general phases can be identified that are likely to occur. Following impact, the thermal pulse delivered by the impactor will heat the surrounding rock. High-temperature hydrothermal fluids generated in the modified thermal environment (Osinski et al., 2001) may, in the early stages following impact, provide a habitat for thermophilic and hyperthermophilic (heat-loving) microorganisms. For example, in the Houghton impact structure, a 24-km diameter structure on Devon Island in the Canadian High Arctic, the hydrothermal system may have lasted for at least 10,000 years. The crater cavity formed during the impact acts as a hydrologic depression and will provide a new habitat for aquatic life (either freshwater on land or marine if the impact occurred in the ocean and excavated a new salt-water filled environment).

Following impact, intracrater lacustrine ecosystems become established, depending upon the size of the structure. Even today, many ancient impact craters support lakes. The biota associated with impact crater lakes has now been studied in several cases. For example, the low biomass and poor diversity of the 3.4-km-diameter New Quebec Crater in Canada and the 18-km-diameter El'gygytyn crater in Siberia (Gronlund et al., 1990; Cremer and Wagner, 2003), contrast with the rich, abundant bacterial and algal ecosystem associated with the 1-km-diameter Tswaing impact crater in South Africa (Ashton and Schoeman, 1983; Schoeman and Ashton, 1982) (Figure 1). The Tswaing crater is situated in South African bushveld and receives organic input from the rich

Asteroid and Comet Impacts, Table 1 Information on the craters discussed in this article

Name of crater	Country	Size of crater (km)	Age of crater (Myr)
Chesapeake	Virginia, USA	90	35.5 ± 0.3
El'gygytyn	Russia	18	3.5 ± 0.5
Houghton	Canada	24	39.0
Lockne	Sweden	7.5	455
Mjølner	Norway	40	142.0 ± 2.6
New Quebec	Quebec, Canada	3.44	1.4 ± 0.1
Ries	Germany	24	15.1 ± 0.1
Tswaing	South Africa	1.13	0.22 ± 0.05

Asteroid and Comet Impacts, Figure 1 Impact crater lakes. Two examples of lakes formed in the cavity excavated by two impact events. El'gygytgyn in Siberia (left) and New Quebec in Canada (right).

vegetation that grows within the impact crater cavity. The area is characterized by erratic rainfall (between 400 and 750 mm a year) and summer temperatures that vary between a mean minimum and maximum of 14.2 and 35.2°C, respectively. The New Quebec crater is in a cold environment; temperatures are relatively constant at approximately 2.5–3°C down to the bottom (267 m) of the lake. Although the biota that takes advantage of an intra-crater lake will be influenced by the local climatic regimen, these examples show how impact excavation provides benefits for life by forming a cavity, in which water collects.

Once the crater begins to cool, exposed melt rocks can provide a substrate for primary succession (Cockell et al., 2001). The drainage of the lake by the breach of the crater wall will expose impact lithologies which then provide a substrate on which colonization can occur. Thus the sequence of geobiological events that occur after impact will be influenced by the general characteristics of impact craters (e.g., presence of a thermal pulse, an impact cavity) and the specifics of any given crater (e.g., duration of thermal pulse, local climate, size and depth of intracrater lake, substrate into which impact occurs, and the scale of the impact).

Ultimately a crater will become buried or eroded to point where the internal ecology may be indistinguishable from the exterior ecology.

As three-quarters of the Earth is ocean, most impacts occur in water and one initial effect is the large-scale movement of water bodies. Investigations of strata in a corehole 30 km northeast of the Mjølner crater, formed in the late Jurassic by the impact of an object into the 300–400-m deep paleo-Barents Sea, suggest that the impact event mixed water masses and caused a large introduction of nutrients into the Sea (Smelror et al., 2002). High concentrations of marine algae suggest that the increase in the availability of ammonia, nitrates, phosphates, and iron contributed to a postimpact bloom. The backwash of a tsunami, caused by the impact, is postulated

to be the reason for the high concentrations of freshwater algae in the strata. The mixing of the water, caused directly by impact, would also have been exacerbated by the collapse of the crater after formation.

Geomicrobiological influence of impacts

In the sense that impacts merely create a “hole in the ground,” their aquatic ecosystems may be indistinguishable from any topographic low in a similar location. However, it is evident that asteroid and comet impacts can have an important influence on the target lithology that is quite specific to impact and can alter the habitat for rock-dwelling microorganisms, making impact craters an important site for geomicrobiological investigations (Cockell et al., 2002). The temperatures and pressures of impact commonly increase the fracture space within rocks, which provide a greater abundance of habitats for endoliths, i.e., organisms which inhabit cracks within rocks. In some instances, the increase in permeable space within the target material in combination with an increase in the translucence of the rock in the visible part of the spectrum can yield new habitats suitable for phototrophs. Impact-shocked Precambrian gneiss in the Haughton crater has been shown to preferentially offer cryptoendolithic habitats for photosynthetic cyanobacterial colonists (Figure 2). The rock is not otherwise a suitable habitat for them (Cockell et al., 2002). This finding constituted empirical evidence for the formation of a microbial habitat specifically by an asteroid or comet impact.

The fate of highly porous substrates versus low porosity substrates during impact is different (Kieffer, 1971). In the former case more of the impact energy must be taken up in pore collapse. Thus, an examination of the effects of asteroid and comet impacts on the colonization of porous sedimentary target lithologies can provide a model with which to understand more generally the effects of impacts on the colonization potential of rocks (Cockell et al., 2005). In a study of impact-shocked sandstones from the

Asteroid and Comet Impacts, Figure 2 Cyanobacterial communities living in impact-shocked gneiss from the Houghton impact crater, Devon Island, Canadian High Arctic (left) and within class 3 shocked sandstones from the same crater (right). Scale bars 1 cm.

Houghton impact structure, Canadian High Arctic, it was shown that shock pressures from 0 to ~ 10 GPa caused the pore structure to collapse, thus rendering the material less amenable to microbial colonization. However, as shock pressures are increased to ~ 50 GPa the material becomes successively better for colonization on account of the formation of vesicular regions in the rock from rock fracturing and melting, improving conditions for colonization. At higher shock pressures colonization potential is again decreased as a solid glass is formed which is impermeable, although potentially still accessible to rock-boring microorganisms.

Thus, in summary, we can say that in general impact events may have the effect of turning lithic habitats on their head. Habitats that were previously impermeable become better sites for colonization as the rocks are fractured. Habitats that were good sites for colonization are rendered less permeable because of pore collapse, although, as the sandstones of Houghton illustrate, the effects on any given lithology tend to be complex.

Within and around impact craters new minerals can be generated in hydrothermal systems that later become habitats for life. Gypsum deposits laid down in the Houghton crater have become a habitat for cyanobacteria which inhabit the inter-sheet spaces between the sulphate crystals (Parnell et al., 2004). The extent to which these organisms are active is uncertain, but they must certainly be halotolerant.

During impact, the target lithology, especially if it is stratified and diverse, will be fragmented and mixed, leading to a heterogeneous substrate in which diverse geochemical sources of nutrients are brought into close proximity. A study of the weathering of a tsunami surge deposit in the Lockne impact crater in Sweden (formed ~ 455 million years ago) showed how lichens preferentially first colonized the soft chlorite clasts incorporated into the impactite (Cockell et al., 2007). The dissolution of the calcium carbonate clasts by fungi and other

organisms creates cavities in the rock, enhancing weathering and causing the rock to exfoliate in sheets. Previous studies on the chemical weathering of impact-shocked rocks from the Ries crater, Germany, showed that the deformation features introduced into quartz were sites of preferential weathering (Leroux, 2005). Diverse impact-generated lithologies can be used as a model to understand microbial weathering of other mixed sedimentary lithologies such as greywackes and microbe–mineral interactions in extremely disturbed geological settings in general.

Most of the geobiological studies conducted to date pertain to the surface environment. The first drill core retrieved from an impact crater with robust microbiological contamination control came from the Chesapeake Bay Impact Crater and was retrieved during the ICDP (International Continental Drilling Project)-USGS (United States Geological Survey) deep drilling project in 2005 (Gohn et al., 2008). A core of length 1.8 km was retrieved. The sequence included a 600 m sequence of postimpact sediments laid down since the impact in the late Eocene and 1.2 km of postimpact tsunami and “fall-back” deposits laid down in the crater cavity immediately after impact. This work has shown that the microbial diversity and abundance of microorganisms correlates to the lithologies in the crater cavity, showing that impacts can significantly disrupt the characteristics of the deep biosphere.

Impact events and astrobiology

The study of the geomicrobiology of impact craters provides useful clues to the opportunities for life on the Archean Earth since the emergence of life ~ 3.5 Gya ago, when the impact flux were higher than today. The formation of hydrothermal systems and the fracturing of rocks are two such opportunities that impact craters might have offered to early life. Insofar as asteroid and comet

impacts are universal (in that no solar system-forming process is known that is completely free from remnant material), habitats created in craters yield insights into the possible habitats for life on other planets, such as Mars. In particular, the likelihood that impacts melt permafrost, or generate deep fracturing into regions of a planet where liquid water is available, suggests that they offer intriguing possibilities as sites to examine the potential habitability of Mars, past and present.

Summary

Asteroid and comet impacts can cause global environmental perturbations through gross changes in atmospheric chemistry. However, much more commonly they alter geobiology at local scales. Through local disruptions of hydrology and geology, they generate new habitats and substrates, the most conspicuous being intracrater lakes. The energy delivered during impacts can also change habitats at the micron scale through changes in target lithology creating entirely novel geomicrobiological environments which, through pressure and temperature effects, are distinguishable from volcanic and other disturbed environments. The geobiological study of asteroid and comet impacts completes our picture of the role of catastrophic disturbance in influencing life on Earth alongside terrestrially mediated mechanisms of environmental change.

Bioastronomy; Exobiology

Definition

Astrobiology is the interdisciplinary science that studies the origin, evolution, distribution, and future of life in the Universe. It is a highly interdisciplinary field that engages many scientific disciplines, including biology, biogeochemistry, paleontology, earth and atmospheric sciences, planetology, and astrophysics among others.

Historical perspective

Astrobiology as a term was first coined in the 1940s to encompass early scientific ideas about how to explore for extraterrestrial life (Dick and Strick, 2004). During the 1960s, astrobiological research was focused more

Astrobiology, Figure 1 The ALH8400 meteorite was discovered in 1984, in the Allan Hills of Antarctica, where it had emerged from glacial ice. In the early 1990s, the meteorite was subjected to a battery of studies by a team at NASA Johnson Spaceflight Center (McKay et al., 1996). The group suggested that they had discovered evidence in the meteorite that was consistent with the presence of fossilized microorganisms. Most of the evidence for a Martian biology was associated with orange-colored globules of iron carbonate shown in this image (the image is about 5.5 cm across). Subsequent studies by the broader science community have shown that the suggested lines of evidence for life in the meteorite are more likely to be a result of inorganic processes that mimic the signatures of life.

narrowly than today, with an emphasis on the origin of life, and programs funding these activities developed under the umbrella term “exobiology.” This early period of activity culminated in the Viking mission to Mars, which carried life detection experiments designed to explore for life in Martian surface materials (Klein et al., 1976). With the failure of the Viking experiments to detect unambiguous evidence for life on Mars, interest in the search for life elsewhere in the solar system waned. Then in 1995, Dr. Wesley Huntress, who was the National Aeronautics and Space Administration’s (NASA) Associate Administrator for Space Science at the time, reintroduced astrobiology to refer to a broad range of scientific activities that had begun to coalesce around questions of the potential for habitable environments and life beyond Earth. The following year, growth of the field of astrobiology was accelerated by the announcement by a team of scientists at NASA Johnson Space Center of possible signs of life in Martian meteorite, ALH84001 (McKay et al., 1996) (Figure 1). With this came a renewed interest in the search for Martian life. Over the next few years, NASA expanded research to develop more reliable approaches to extraterrestrial life detection, which helped to revitalize the field of astrobiology.

In 1998, NASA helped promote the growth of astrobiology by creating the NASA Astrobiology Institute (NAI), a virtual research organization comprised of interdisciplinary teams of scientists from NASA Research Centers and universities around the United States. An

important goal of the NAI has been to promote the growth of astrobiology through the sponsorship of collaborative, transdisciplinary research that could provide a scientific and technology development framework for future space missions. Following the establishment of the NAI, the growing community of scientists converged on a strategic plan that would help guide astrobiological research, including a scientific roadmap, with well-defined goals and objectives, and technology developments that would be needed to enable missions (Des Marais et al., 2008). Since its inception, the astrobiology roadmap has been revised and updated every few years to reexamine scientific priorities in the light of new scientific discoveries. The NAI has also embraced partnerships with other astrobiology institutions in Spain, Australia, and Great Britain. This includes international cosponsorship of yearly workshops designed to promote collaborative research and train the next generation of astrobiologists. Maturing of the field is also apparent in the development of two international journals for Astrobiology, international conferences each year and the establishment of an Astrobiology Society.

In 2008, the National Research Council reviewed the growth of the science of astrobiology (NRC, 2007a), summarizing the important collaborative efforts and scientific discoveries that had occurred since the inception of the NAI in 1998. Studies of the deep geological record of Earth have helped refine our knowledge of the early evolution of life on Earth, based on the fossil record, while providing new constraints on the nature and evolution of early environments. Studies of prebiotic organic chemical systems have revealed important new insights into the steps that may have preceded the emergence of terrestrial life, as well as the environments where life may have emerged (Russell et al., 1993; Deamer et al., 2002; Ricardo et al., 2004; Ferris, 2005).

Environmental limits for life

Biological studies have also significantly expanded our knowledge of the environmental limits of life on Earth (see Rothschild and Mancinelli, 2001), while the application of new tools of environmental molecular microbiology have revealed the presence of an extraordinarily diverse microbial biosphere, with an equally impressive array of metabolic strategies for extracting energy from Earth’s environments (e.g., Staley and Reysenbach, 2001). Life has been shown to occupy a broad range of temperature (-15°C up to 122°C ; see Kashefi and Lovely, 2003; also, Figure 2 from Takai et al., 2008) and nearly the full range of pH from acidic to alkaline ($\text{pH} \sim 1.0$ to 13.0), over a range of salinities from freshwater to hypersaline brines and water activities >0.6 . We have also learned of the importance of the deep subsurface biosphere, which may account for possibly half or more of the Earth’s biomass (Gold, 1998). The discovery of lithoautotrophs that can use the simple chemical compounds, such as hydrogen and methane (CH_4), released

Astrobiology, Figure 2 Life is known to exist over a broad range of physical and chemical conditions and uses an equally impressive array of metabolic processes for extracting energy from the environment. This image was obtained using a fluorescence microscope. The form shown is known as *Methanopyrus kandleri* and is a hyperthermophile (growth optimum $>80^{\circ}\text{C}$) that uses carbon dioxide and hydrogen for its metabolism, producing methane as a by-product. The species was discovered at a submarine hydrothermal vent in the Gulf of California, living at temperatures between 84°C and 110°C . Strain 116 of this species has been shown to grow up to 122°C and survive up to $\sim 130^{\circ}\text{C}$. This is currently the highest temperature organisms known (Kashefi and Lovely, 2003; Takai et al., 2008). Each cell in this image is only a few microns in length.

during the low-temperature inorganic weathering of rocks or sulfide (H_2S) formed by hydrothermal processes has opened up opportunities for the survival of microbial life in the deep subsurface, independent of photosynthesis (Stevens, 1997). These discoveries and others in the fields of biology and paleontology have helped broaden the search space for habitable environments and life elsewhere in our Solar System and beyond.

Defining life

Earth has the distinction of being the only place in the Universe where life is known to exist. Thus, terrestrial life provides a logical starting point for evaluating the prospects for the existence of life elsewhere and identifying strategies for astrobiological exploration. For exploration, we need to identify basic attributes of living systems that can be used to inform exploration strategies to search for life beyond the Earth. Ideally, we would like to follow universal criteria that are not tied to the particular circumstances found on Earth. But, universal definitions of life have proven elusive and challenging to apply

Astrobiology, Figure 3 In nature, amino acids come in right- and left-handed forms called isomers that are identical in composition and differ only in structure. On Earth, amino acid isomers occur in nature in equal abundances (i.e., racemic mixtures). However, when making proteins, organisms select only left-handed amino acids. While the origins of chirality remain unclear, some have suggested that this unique property of terrestrial life may provide a useful signature for identifying life on other worlds.

(Cleland and Chyba, 2002). As a practical approach to exploration, the search for life begins with what is known of terrestrial life, following a terracentric definition that combines features like a water-based carbon chemistry, and self-replication, with cellular systems that evolve through processes of Darwinian natural selection to adapt to environmental changes. Although such attributes are regarded as essential properties of life, many inorganic systems display similar features, such that a single property, while necessary, is not regarded as sufficient to define life. Methods of life detection for astrobiological exploration of other planetary environments are still in their infancy but presently combine several instrumental techniques that can independently measure life's attributes, as a basis for detection. An example is the Pasteur instrument, which combines the detection of amino acids in soils and ices, with measurements of the chirality (right- versus left-handedness) in amino acid building blocks of proteins (Skelley et al., 2005). Terrestrial life selects left-handed amino acids when making proteins, and this selectivity has been suggested to be a biosignature that could be used to explore for life elsewhere (Figure 3).

Exploring for life in the Solar System

In exploring for life in the Solar System, NASA has adopted a simple approach that emphasizes the search for those environmental factors that are known requirements of terrestrial life. At the top of the list is liquid water, which is required by all known life-forms. In their exploration of the Solar System and beyond, NASA has pursued an exploration strategy designed to "Follow the Water."

Liquid water plays an essential role in living systems as a medium of biochemical transport and exchange during metabolic reactions. The unique solvent properties of liquid water are primarily derived from the dipolar charge distribution of water molecules and the ease with which hydrogen bonds may be formed and broken in solution. These properties also determine many of the unique physical properties of water, including the broad temperature range, over which it remains liquid and the decrease in density that occurs upon freezing. This has the interesting consequence that the crystalline structure of water expands and density decreases during freezing, so that the ice floats at the surface instead of sinking to the bottom. Thus, oceans freeze from the top down, thereby enhancing long-term habitability. Terrestrial examples that illustrate the importance of this for habitability include perennially ice-covered lakes of the “dry valleys” of Antarctica. High salinity (which depresses the freezing point), combined with the self-insulating properties of the frozen surface of the lake, promotes the persistence of habitable zones of liquid water environments, even in the winter when air temperatures have fallen far below the freezing point (Andersen et al., 1995). On Mars, one consequence of this is that ice-covered lakes could have persisted on Mars long after the planet began to lose its atmosphere, thus rendering liquid water at the surface unstable (Wharton et al., 1995; McKay and Davis, 1991). Recent climatic variations on Mars mediated by

changes in the obliquity and recorded in polar deposits, suggests the possibility that transient habitable conditions could have developed at the Martian surface very recently in the planet’s history (Figure 4).

It is also widely appreciated that living systems require more than liquid water. Habitable environments are also sources of the biological elements (C, H, N, O, P, S), inclusive of about two-dozen transition metals that are critical for enzyme function (Crabb and Moore, 2009), and sources of energy for sustaining cellular metabolism, growth, and replication (Hoehler et al., 2007). Thus, the exploration for potentially habitable zones in the Solar System and beyond has been focused on the search for environments where liquid water coexists with sources of biogenic elements and energy (Figure 5).

Recent progress in astrobiology

In parallel with the studies of life on Earth, missions to other bodies in our Solar System have revealed many examples of potentially habitable environments, with evidence for the past, or present existence of liquid water, biologically important elements, and potential energy sources. The exploration of Mars has identified

Astrobiology, Figure 4 The High Resolution Stereo Camera (HRSC), onboard the European Space Agency’s Mars Express Orbiter, acquired this image of the Chasma Boreale region of the northern polar cap of Mars. Erosive winds carved the large canyon, Chasma Boreale, cutting deeply into polar deposits and exposing a record of past climate changes. The image shows finely layered, ice-rich sedimentary sequences that appear to reflect cyclical obliquity changes in the climate of Mars, occurring over the past few hundred thousand years. This caused the polar caps to wax and wane, affecting the habitability of the planet’s surface.

Astrobiology, Figure 5 In January 2004, the Mars Exploration Rover (MER) mission landed twin rovers on the surface of Mars to explore for evidence of ancient habitable environments. The Opportunity Rover, which landed at Meridiani Planum, discovered unequivocal evidence of past water in the form of sulfate minerals, which only form in the presence of water (Knoll et al., 2005). This image, taken by the MER Opportunity Panoramic Camera (Pancam), shows light-toned slabs of sulfate-rich sedimentary rocks that have been partially buried by migrating sand dunes. (Image Credit: NASA.)

Astrobiology, Figure 6 During a close flyby, the Galileo spacecraft imaged the surface of Europa, one of the moons of Jupiter, showing a pervasively fractured surface composed of water ice that has apparently formed by the upwelling of warm ice and/or brines, from deep within the moon's interior. The internal energy believed to drive melting has been attributed to tidal flexing of the interior due to gravitational forces from Jupiter and the other moons that orbit the planet. Whether there is a global subsurface ocean on Europa, or warm, convecting ice is still uncertain, but magnetometer experiments onboard the Galileo Orbiter suggest the presence of subsurface brines (Kivelson et al., 2000). (Image Credit: NASA.)

widespread geological evidence for climatic changes that could have affected ancient surface water systems, while also strengthening the case for liquid water in the subsurface today (NRC, 2007b). NASA missions have also “followed the water” to the outer Solar System, with the discovery of brines beneath the surfaces of three of the icy Galilean satellites of Jupiter (Europa, Ganymede, and Callisto; Kivelson et al., 2000; Greenberg, 2008), as well as Enceladus, one of the moons of Saturn (Kieffer et al., 2006). In addition, Saturn's moon, Titan, has also been shown to harbor water ice as well as lakes of liquid methane (Mitri et al., 2007) (Figure 6).

The discovery of lakes of methane on Titan has led to a debate over the potential for life to originate within highly reducing, hydrocarbon-rich environments, where liquid water may be replaced by alternative solvents, such as liquid methane or ammonia, as alternative solvents for life processes (e.g., Benner et al., 2004) (Figures 7 and 8).

Finally, discoveries in observational astronomy have shown that planets and planetary systems to be common features of other stars in the nearby Milky Way Galaxy. Since the first confirmed discovery in 1992, more than 450 extrasolar planets have been identified, and the number continues to grow each year (Schneider, 2010). Orbiting planets have been detected by a variety of methods, but primarily by measuring small perturbations in the position of the parent star due to the gravitational tug and pull of an orbiting planet(s), or as a result of slight

Astrobiology, Figure 7 The Cassini-Huygens mission to Saturn has revealed the presence of hydrocarbon lakes on the surface of Saturn's moon, Titan. Beyond Earth, these are the only other lakes in the Solar System. Yet, they are composed of liquid methane and other hydrocarbons – not water (Mitri et al., 2006). This discovery has led some scientists to consider the possibility that liquid hydrocarbons such as methane or ammonia might provide alternative solvents to sustain life-forms quite different from those found on Earth. (Image Credit: NASA.)

decreases in the stars brightness as an orbiting planetary body passes in front of the star. More rarely, extrasolar planets have also been discovered using direct imaging methods (Figure 9).

Summary

The emerging field of astrobiology is taking a highly interdisciplinary approach to the basic question: “Are we alone in the Universe?” An answer to this question is being pursued on a large number of fronts both within and beyond our Solar System. For example, studies of biology on Earth has continued to expand the environmental limits for life while revealing a dizzying array of potential energy sources. This has significantly expanded the potential number of habitable zones in the solar system, opening up new opportunities for astrobiological exploration in the solar system. Ongoing exploration of the planet Mars, long regarded as most Earth-like in its potential habitability, has provided abundant evidence for past water on the

Astrobiology, Figure 8 Enceladus, a moon of Saturn, imaged during flybys of the Cassini orbiter, has been shown to actively erupt plumes of water ice, vapor, and organic compounds from the moon’s interior (Kiefer et al., 2006). These eruptions occur along fracture systems located near the south pole. (Image credit: NASA.)

planet’s surface, along with potential building blocks for life and sources of energy to support living systems. Although the present surface of Mars appears to be uninhabitable due to an absence of liquid water, life could still exist in the subsurface (Warner and Farmer, 2010), or its remains be preserved in ancient aqueous sediments exposed at the surface (Farmer, 2000; Farmer and Des Marais, 1999). Future exploration will continue to pursue the search for fossil or extant biosignatures of microbial life on Mars, in the hope of making a transformative and revolutionary discovery of life. But exploration is also pursuing the question of microbial life in potentially habitable icy moons of the outer Solar System, specifically three of the Galilean moons of Jupiter (Europa, Ganymede, and Callisto), as well as Saturn’s moon, Enceladus, where internal zones of liquid water are maintained not by solar radiation but by the internal tidal heating resulting from gravitational flexing of the interior of these moons. In addition, Jupiter’s moon, Titan, has provided access to potentially habitable environments that are fundamentally different from Earth. On Titan, we have discovered alternative environments potentially capable of supporting non-terran forms of life, sustained by alternative solvents (oceans of liquid methane and ammonia) and energy sources. Finally, the discovery of numerous planets and planetary systems orbiting other stars in the nearby galaxy has widened the search for habitable environments beyond the confines of our Solar System. These and other important discoveries have shaped the way astrobiologists evaluate potential for the origin, evolution, and persistence of life elsewhere, contributing to the development of a robust conceptual framework for planning missions and developing the technologies needed to explore for extraterrestrial life (e.g., Mix et al., 2006; Plaxco and Gross, 2006; Sullivan and Baross, 2007).

Astrobiology, Figure 9 Fomalhaut b is a multiple Jupiter-mass planet that was directly imaged in its orbit around the star Fomalhaut, located about 25 light years away from Earth in the constellation Piscus Austrinus (Kalas et al., 2008).

Summary

Salinity is not fixed by any equilibria, feedbacks, or geochemical cycles and appears to have been generally higher in past times. It is apparently a free variable dependent upon the vagaries of intermittent salt (and brine) sequestration on long-lived continental cratons. Ocean salinity declines when the salt and brine accumulate and rises when they are eroded back into the sea. Sequestration seems to have been enhanced following breakup of the two supercontinents in Earth history. These breakups are, in turn, driven by the vagaries of mantle convection. The combination of processes therefore necessary to lower the initial, pre-continent high salinity and to affect the rise and fall of ocean salinity involve a long chain of independent variables. The role of chance and contingency in biologic evolution has long been recognized. The low odds that a rerun of the tape of evolution would yield the same results have been duly noted (Gould, 1990). The same might be said about the evolution of oceanic salinity. Salinity history should therefore probably be added to all those chance occurrences that have likely affected the course of biologic evolution.

SCANNING PROBE MICROSCOPY (INCLUDES ATOMIC FORCE MICROSCOPY)

Michael Hoppert

University of Göttingen, Göttingen, Germany

Synonyms

Atomic force microscopy; Atomic probe microscopy; Force microscopy; Scanning force microscopy

Definition

Scanning probe microscopy uses a nanoscopic probe that is scanned over a solid surface. The interaction between the probe and the surface may be a mechanical or electromagnetic force. The force signal is enhanced and then composed to a force diagram of the surface. Under ideal conditions, an atomic-scale resolution may be achieved.

Introduction

Since their development during the 1970s and early 1980s, scanning probe microscopes (SPMs) have developed into instruments suitable for the analysis of surface topography (and other surface properties) down to near-atomic resolutions. All instruments belonging to this family contain essential components as depicted in [Figure 1](#). In the scanning process, surface material properties are mapped in all three directions. The essential parts of the system are the sharp scanning probe tip, which moves in the *z* direction, a piezoelectric scanner that moves the specimen, or, alternatively, the tip, in the *x/y* directions, and a sensor for tip positioning. Sensor and tip are connected in a feedback loop for the correction of *z* positioning. The *x/y/z* positions are used to generate a topographic image of the specimen. The resolution of SPMs is only limited by the size of the probe tip (or the probe-sample interaction volume). Since the tip apex ends up in one single atom and the piezoelectric actuators execute motions down the range of angstroms, resolutions down to atomic scale are possible. In contrast to electron microscopes, the sample can be observed under ambient conditions, which makes the technique potentially attractive for life science, including geobiological research.

The scanning tunneling microscope (STM)

The scanning tunneling microscope (STM) is the ancestor of all SPMs (Binnig et al., 1982). The specimen needs to be conductive or semiconductive. STM is predominantly used in materials sciences and chemistry. Though not ideally suited for biological specimens, the technique has also been used in life sciences (see, e.g., Guckenberger et al., 1988). The instrument provides a surface topography down to atomic resolution.

STMs use a sharpened conducting tip with a bias voltage (in mV to V-range) applied between the tip and the sample. If the distance between the tip and the sample is large, no current flows. When, however, the tip is brought

Scanning Probe Microscopy (Includes Atomic Force Microscopy), Figure 1 Basic setup of a scanning force microscope.

very close (1 nm), but without physical contact, a small current (pico- to nano-amperes) flows across the gap between the tip and the sample. This current is the result of the overlapping of wave functions between the tip atoms and the surface atoms. Electrons can “tunnel” across the vacuum barrier separating the tip and sample in the presence of the bias voltage. The magnitude of the tunneling current increases exponentially when the tip approaches the specimen surface. This results in high system sensitivity: when the separation between the tip and the specimen changes by 10%, the tunneling current changes by an order of magnitude. This provides, in the end, surface images with lateral atomic resolution. The image of the tunneling current depicts approximately the topography of the sample. Actually, rather than physical topography, the STM measures a surface of constant electron tunneling probability.

Atomic force microscopy and related techniques

Atomic force microscopy (AFM) comprises several derivatives and is applicable for measurement of numerous physical and chemical parameters of sample surfaces. AFM in the strict sense (without a modified probe tip) is used to study the material properties of specimens (stiffness, plasticity, and viscosity; see, e.g., Rotsch et al., 1997). For biological specimens, on the cellular level, the properties of the cytoskeleton and (induced) cytoskeletal changes become visible (see Fung, 1993; Goldmann et al., 1998 for some applications). With the aid of chemically modified tips, AFM is useful for quantification of binding forces between receptors and ligands, protein

complexes and cells (Lehenkari and Horton, 1999; Yip, 2001; Allison et al., 2002; Dufrene, 2008). Since AFM is generally suited for solid surfaces, it is especially a versatile tool for the observation of biomineral formation down to nanoscale in situ (see, e.g., Hildebrand et al., 2008).

Image formation in AFM is generally determined by sensing of interatomic forces, making the technique applicable to all solid specimens. Similar to STM, the AFM probes the surface of a sample with a sharp tip, less than 10 nm in diameter. The tip is located at the free end of a 100–500 μm long cantilever. The cantilever is deflected by forces between the tip and the sample surface, and a detector measures the cantilever deflection as the tip is scanned over the sample (or the sample is scanned under the tip). The measured cantilever deflections are used to generate a map of surface topography (Figure 1). Conductors, semiconductors, and insulators may all be scanned. Resolution in the atomic range requires rigid specimens; hence, for most biological samples (except for biominerals), maximum resolution is not achievable.

The topographic data set necessary for image formation can be directly obtained from the measurement of cantilever deflection. When a laser beam is projected onto the cantilever, the position of the reflected beam is shifted, which results in detection of even sub-nm movement at the tip surface. Other methods of signal enhancement are based upon optical interference (e.g., by a Michelson interferometer). A STM tip may also be used to read the cantilever deflection. If the cantilever is made from a piezoresistive material, its deflection can also be detected electrically.

When the cantilever deflection is detected, this can be used to generate the topographic data set directly. This mode (constant height) is often used for producing atomic-scale images of atomically flat surfaces, for which the cantilever deflections and variations in applied force are small. The constant height-mode is also essential for recording real-time images of changing surfaces, which requires high scan speeds. Alternatively, the deflection of the cantilever can be used in a feedback loop that moves the scanner up and down in the z direction, responding to the topography, by keeping the cantilever deflection constant. In this case, the image is generated from the scanner's motion. With the cantilever deflection held constant, the total force applied to the sample is constant. This mode (constant force) is generally preferred for most applications.

Figure 2a depicts the typical force–distance curve for AFM. As the atoms of the tip and the specimen surface are gradually brought together, they first weakly attract each other by van der Waals forces. This attraction increases until the electron clouds of the atoms are so close together that their electrostatic repulsion progressively weakens the attractive force. The force becomes zero when the distance between the atoms reaches a couple of ångströms, about the length of a chemical bond. In the *contact mode*, the cantilever is held less than a few ångströms from the sample surface, and the interatomic force between the cantilever and the sample is repulsive. For biological (i.e., soft and wet) objects, the contact mode may induce several artifacts. This is avoided by application of modes in which less force is applied to the specimen. However, smaller forces also have to be detected, which in practice reduce the final resolution. In the *noncontact mode*, the cantilever is held of the order of tens to hundreds of ångströms from the sample surface, and the

interatomic force between the cantilever and sample is attractive (largely as a result of long-range van der Waals interactions). In this mode, the cantilever is oscillated with a frequency of 100–400 kHz (the resonance frequency of the cantilever) with an amplitude of a few tens of nanometers. The resonance frequency of the cantilever varies with the force gradient acting on the cantilever. These variations can be used as a measure of changes in the force gradient, which in turn reflects the changes in the tip-to-sample distance, or sample topography. The resonant frequency or vibrational amplitude of the cantilever is monitored and kept constant with the aid of the feedback loop that moves the scanner up and down in the z direction. The system also keeps the average tip-to-sample distance constant. As in contact AFM (in constant-force mode), the motion of the scanner is used to generate the topographic data set. It thus detects changes in the resonant frequency or vibration amplitude as the tip comes near the sample surface. *Intermittent-contact* (or tapping mode) AFM is similar to noncontact AFM, but the vibrating tip is brought closer to the sample in such a way that the sample is intermittently contacted or “tapped.” As in noncontact AFM, the oscillation amplitude of the tip also changes in response to the distance between tip and sample. Intermittent-contact AFM is also less likely to damage the sample than contact AFM. Though it touches the specimen, lateral forces (friction or drag) between the tip and the sample are minimal. The *pulsed force mode* (PFM) is used to monitor, besides sample topography, stiffness and adhesion simultaneously (Krotil et al., 1999). In PFM, the probe scans the surface in contact mode. When the cantilever is oscillated with a frequency of about 1 kHz, it is possible to analyze the force output as a function of the distance between the tip and the surface. The force output is depicted in Figure 2b. During an oscillation

Scanning Probe Microscopy (Includes Atomic Force Microscopy), Figure 2 (a) Force–distance curve in atomic force microscopes. (b) Force curve in the pulsed force mode (PFM). Important features of the curve are marked with blue dots.

cycle the probe tip is attracted by the surface and “snaps” into contact at a certain distance. The tip is then pushed further to the sample, the force signal increases, whereby the slope of the curve depends on the specimen stiffness. When the distance increases, force signal decreases, the tip loses contact (adhesion peak) and oscillates freely until the signal is damped to the baseline. Characteristic points of these curves are taken for processing to generate simultaneous topographic, stiffness (deformation of the specimen under an applied force), and adhesion maps. In the lateral force mode (LFM), lateral deflections (twisting) of the cantilever are measured. These are caused by forces on the cantilever parallel to the plane of the sample surface. LFM studies are used to detect surface friction arising from inhomogeneity in surface material; an artificial enhancement of edges in the image may also be achieved (Overney et al., 1992). In the force modulation mode (FMM), the elastic properties of a specimen are mapped. The cantilever tip is scanned in contact with the sample surface. As in constant-force contact AFM, the feedback loop uses the cantilever deflection signal to maintain a constant force between the tip and the sample and to generate a topography image. When a periodic oscillation is applied to the tip or the sample, the sample surface resists and the cantilever bends according to the elastic properties of the sample surface. The system generates an image, a map of sample stiffness, from the changes in the amplitude of cantilever modulation (Troyon et al., 1997).

Scanning force microscopy is a highly variable technique, because forces between a specimen and an AFM tip may be caused by a multitude of underlying factors. A modified scanning tip may therefore be used to measure a variety of parameters other than the described surface forces. In life sciences, the detection of chemical properties on biological surfaces is of outstanding interest. Some derivatives of AFM, mainly based on a modified scanning tip, are listed below.

Magnetic force microscopy (MFM) is used for measuring the magnetic force between the tip and the sample. For MFM, the tip is coated with a thin ferromagnetic film. The system mostly operates in noncontact mode and detects magnetic domains down to a resolution of approximately 20 nm (de Lozanne, 2006).

Electrostatic force microscopy (EFM) measures the forces originating from an electrical field between the AFM tip and the sample. When a voltage is applied between the tip and the sample (the tip is not in contact with the surface), the cantilever deflects when it scans over charged particles on the sample surface. In this way, EFM maps locally charged domains on the sample surface (Girard, 2001).

Scanning thermal microscopy (SThM) measures the specimen temperature and thermal conductivity of the sample surface. The SThM tip may be made from a thermocouple temperature sensor: a pair of dissimilar metals joined at the tip (platinum/silver Wollaston wires). The temperature difference between the tip and the open end generates a proportional net voltage. In this way, thermal

data and surface topography (with the conventional AFM force feedback mechanism) can be measured at the same time. Probes made of Wollaston wires also operate as active heat sources. The probe resistance is proportional to the probe temperature. Changes in the current required to keep the probe at constant temperature produce a thermal conductivity map. When the tip is held at a constant current, the specimen temperature is mapped by changes in the probe resistance (Price et al., 1999).

Photothermal microspectroscopy (PTMS) combines scanning probe microscopy at a submicron spatial resolution with an IR interferometer. IR radiation from a Fourier-transform spectrometer is focused on a specimen. IR absorption causes stretching and bending of molecular bonds. Upon relaxation of these molecular vibrations, evanescent thermal waves are emitted. This signal is detected with a Wollaston wire (SThM) probe. The resulting temperature fluctuations are converted to electrical signals, recorded as a function of time and amplified to produce an “interferogram” which can be transformed back to give a conventional spectrum as in other forms of FTIR spectroscopy. In PTMS, resolutions down to 10 μm are achievable, whereas in conventional FTIR microspectrometric devices, only 100 μm are possible (Grude et al., 2007).

Phase detection microscopy (PDM) is another variation for mapping of surface properties such as elasticity, adhesion, and friction. Unlike FMM (see above), the technique operates in the noncontact mode, which is more suitable for less rigid (biological) samples. The technique monitors the phase lag between the signal causing the cantilever to oscillate and the cantilever oscillation output signal. Changes in the phase lag reflect changes in the mechanical properties of the sample surface. The feedback loop in PDM operates in the usual manner, using changes in the cantilever’s deflection or vibration amplitude to measure sample topography. The phase lag is monitored while the topographic image is being taken, so that images of the topography and material properties can be collected simultaneously.

Scanning near-field acoustic microscopy (SNAM) utilizes an ultrasonic quartz oscillator as resonator and at the same time as a sensor of the damping force exerted by the specimen. Damping increases when the tip approaches the surface. The instruments have been especially developed for scanning of larger areas, with a surface relief in the millimeter range. For low resolution, wide probing tips are used. At resolutions of 100 nm, both hard and soft specimens are well suited for mapping. Higher resolution is obtained with sharp AFM tips (Murdfield et al., 1996).

With chemical force microscopy (CFM) it is possible to obtain modified force curves based on specific interactions between molecules on the specimen surface and a sensor molecule on the probe tip. The tip (normally made from silicon or silicon nitride) is modified by coating a very thin metallic film (normally a 5 nm thick chromium layer followed by a 50 nm thick gold layer) onto the probe, followed by immersion of the probe in a solution of an

organic thiol. The molecules form a monolayer, with the thiol group bound to the gold surface. The distal end of thiol molecule contains an appropriate functional group for interaction with the sample surface. Besides small methyl, carboxyl or amino groups, macromolecules may also be used as specific probes. Coupled enzyme proteins may be used to measure enzyme–substrate interactions. In a similar experimental setup, even whole bacterial cells, coupled to the cantilever, were used to measure distance–force curves between the cell surface and biominerals (Lower et al., 2001; Dufrene, 2008 and references therein).

Near-field scanning optical microscopes (NSOMs) are based upon the AFM operating in the noncontact mode. At the same time, the probe tip generates nonpropagating (evanescent) electromagnetic wave fields to excite a specimen at a small (down to tens of nm) surface spot. Most NSOM setups use an aluminum-coated glass fiber with a sub-light wavelength aperture (25–100 nm in diameter) at the tip of an AFM-like scanning probe (Figure 3). Light, guided through the fiber optics, causes an evanescent wave field that decays exponentially with distance from its origin. Evanescent waves interact with the specimen surface, e.g., by excitation of fluorophores. Fluorescence light emitted from the specimen is scattered from the sample, but only from the evanescent wave field region (at distances from the probe tip of approximately one fifth of the light wavelength). The fluorescence signal is conventionally propagating far-field light. This signal may be collected by a conventional optics below the specimen (e.g., an inverted microscope). Because of the extremely small excitation volume determined by the evanescent wave, together with the high-resolution topographical map generated by the AFM tip, a high-resolution map of the fluorescent targets in the specimen is achieved.

With NSOM, the AFM topographic information is combined with optical properties of a specimen, such as

Scanning Probe Microscopy (Includes Atomic Force Microscopy), Figure 3 Hollow fiber tip in a near-field scanning optical microscope (NSOM). At the tip, the evanescent wave field (red) excites a fluorophore marker (yellow). The resulting (far-field) light signal is detected by an external detector. Propagating far-field light (orange arrows).

refraction index, reflectivity, transparency, polarization Raman shift, and fluorescence (Gheber et al., 1998; de Lange et al., 2001; Edidin, 2001).

Conclusion

Scanning probe microscopy introduced a purely surface-related technique with atomic resolution into the field of material sciences and also life science. For the first time it was possible to visualize macromolecules directly, under physiological conditions. Even more important is the application potential for mapping all kinds of intermolecular interactions. The fact that just signals from a surface can be collected may be a drawback for the observation and documentation of most biological processes because they are inside cells and other compartments. Most mechanisms in material science, chemistry and biology are, however, surface-related. It is just the question how a surface, which may also be a membrane or the interface of another compartment, can be prepared in a way that it is reachable by an SPM.

Other limitations are the low scanning speed of most modes and the small obtainable image area. Hence, it is straightforward to combine scanning probe microscopy with other imaging techniques. Correlation of low-resolution techniques including fast image acquisition (fluorescence light microscopy or confocal microscopy) with the high-resolution AFM image may be versatile for a multitude of applications, especially concerning the interaction of organisms with solid surfaces (e.g., Arnold et al., 2004; overview in Haupt et al., 2006).

SEDIMENT DIAGENESIS – BIOLOGICALLY CONTROLLED

Kurt O. Konhauser¹, Murray K. Gingras¹, Andreas Kappler²

¹University of Alberta, Edmonton, Alberta, Canada

²University of Tübingen, Tübingen, Germany

Definition

The biological processes that modify unconsolidated sediment after initial deposition and burial.

Overview

Throughout the sediment column, up to the temperature threshold of life, microbial activity plays an integral role in diagenesis. It is widely recognized that through their various chemoheterotrophic pathways, microorganisms are ultimately responsible for the conversion of organic carbon to CO₂ and CH₄ at temperatures <100°C. Some aerobic bacteria use hydrolytic enzymes to break down complex molecules into simple monomers such as sugars, amino acids, and fatty acids that they can then utilize, while most anaerobes are restricted to simple organic compounds (e.g., acetate, lactate, H₂) that are the by-products of fermentation (Lovley and Chapelle, 1995). Typically, the more labile materials (e.g., proteins, carbohydrates) are degraded in near-surface sediments on time scales of days to years, and more refractory materials (e.g., lipids) are broken down deeper in the sediment on time scales of decades, while the most resistant materials (lignins) are transformed only on timescales of thousands to millions of years. The amount of refractory material left after microbial attack will depend on the nature of the primary producers and the degree of processing that has taken place in the river catchment area or oceanic water column. In the end, for example, <1% of the original material buried into marine sediment may ultimately contribute to the sedimentary organic geochemical record (Emerson and Hedges, 1988).

Pore water and mineralogical changes during diagenesis are directly related to bacterial reduction of soluble (O₂, NO₃[−], SO₄^{2−}, CO₂) or solid-phase (MnO₂ and ferric oxyhydroxides) components in the sediment. The terminal electron accepting processes (TEAPs) that occur at any given layer depends on oxidants that are available and, in the situation when multiple electron acceptors are present (as in the uppermost sediment layers), on the free energy yield of the specific reaction. Thus, the decomposition of freshly deposited organic material in sediments proceeds in a continuous sequence of redox reactions, with the most electropositive oxidants being consumed at, or near the surface, and progressively energetically poorer oxidants being consumed at depth until the labile organic fraction is exhausted and the deeper sediments are left with a composition very different from that of the sediments originally deposited (Figure 1). Inorganic by-products of chemoheterotrophy (e.g., HCO₃[−], Mn²⁺, Fe²⁺, NH₄⁺, NO₂[−], HS[−], HPO₃^{2−} and CH₄) seldom accumulate. Physical and macrofaunal processes will cause the net transport of these reduced species from the deeper layers toward the sediment surface, where residing anaerobic and aerobic chemolithoautotrophic bacteria use them as metabolic reactants. Alternatively, their presence in pore waters may trigger important abiotic reactions between the solid and dissolved phases leading to secondary mineral formation, i.e., cementation.

Oxic zone reactions

The sediment–water interface is the site of most intense heterotrophic activity. Aerobic respiration (Reaction 1) is

Eubacteria (term abandoned)

Definition

Prokaryotes that constitute, besides Archaea and Eukarya, a domain of life. According to (old Greek) bakterion “small rod.”

History

During the nineteenth century, several fundamental discoveries defined the beginning of modern microbiology (cf. Schlegel, 1999). Louis Pasteur (1822–1895) found that growth of bacteria in nutrient broths is not due to spontaneous generation and that fermentation is caused by the growth of microorganisms. Ferdinand Cohn (1828–1898) could state that bacteria must belong to a phylogenetic group separated from other unicellular plants or animals, due to their size, shape, the mode of cell division, and their metabolic properties. Robert Koch (1842–1910) developed the concept of infectious diseases. The final proof that bacteria must be distinct from plants and animals could be shown not until the distinct compartmentation of bacterial cells was noticed by electron microscopy, in the 1960s. Especially, the absence of a nuclear membrane was a clear indicator for some fundamental differences in cellular processes. Hence, the term “prokaryote” for bacteria (including Archaea) was introduced. The separation of *Archaea* from Bacteria (as phylogenetic groups) was achieved by Woese and Fox (1977).

Besides the missing nuclear membrane as a common cytological feature, Bacteria and Archaea are structurally and physiologically distinct. The Bacteria are the phylogenetically most diverse domain, with a rapidly growing number of phyla. Currently, more than 80 phyla could be identified (Pace, 2009). About two-third of these phyla are just represented by rDNA sequences from environmental samples. Twenty-five phyla are represented by known species. Among them, twelve phyla contain the majority of currently known and well-characterized species. The well-known representatives of phyla, however, stand for an incomplete and subjective view on the bacterial domain. Human pathogenic species are, for example, overrepresented, because of their importance for human medicine. The significance of several groups relevant for environmental processes, such as Planctomycetes or the *Roseobacter* clade has just been addressed recently. General knowledge on the physiology of these groups is still limited. Most in-depth analyses on microbial physiology and molecular biology has been performed with selected species from a small number of phyla, such as *Escherichia coli*, *Salmonella*, and *Pseudomonas* species (Proteobacteria) or *Bacillus* (Firmicutes). Some organisms like *Ralstonia* (an aerobic hydrogen oxidizing Proteobacterium) or *Rhodobacter* (a photosynthetic bacterium) are model organisms for environmentally relevant processes.

The phylogenetic tree (Figure 1), based upon 16S-rDNA data shows an overview of these major, well-characterized lineages (Cole et al., 2009; Madigan et al., 2009). In-depth analysis based upon whole genomes may allow, in future, a more accurate positioning of genes and organisms in phylogenetic trees (Ciccarelli et al., 2006; Wu and Eisen, 2008). Though the major phyla have been confirmed, some repositioning may be necessary. Some reports imply that Firmicutes are descendants of

Bacteria, Figure 1 Phylogenetic tree of Bacteria, derived from 16S rDNA sequences. (Redrawn after Madigan et al., 2009.)

the stem group, other than expected from rDNA analysis (Ciccarelli et al., 2006).

In the following chapter, a short survey on the hitherto well-investigated groups will illustrate the metabolic diversity of the organisms. Terms denoting defined phyla are capitalized.

Diversity in phylogenetic lineages

Important metabolic key processes are unique to bacteria and have just been overtaken by endosymbiosis to eukaryotes, such as chlorophyll-dependent photosynthesis and mitochondrial respiration. Thus, metabolism in every eukaryote is based upon bacterial metabolism. Eukaryotes, however, received just a small range of the highly various metabolic features from bacteria. Virtually, every reduced organic compound and numerous reduced inorganic molecules can be oxidized in a bacterial metabolism that may be either respiratory, that is, generating a membrane potential, driven by an electron flow toward an oxidized acceptor (oxygen, nitrate, and others) or fermentative (generation of ATP independent of a membrane potential). These metabolic features are unsuitable to discriminate between large groups because they are mostly not specific for only one phylum (Tables 1–4; Schlegel and Jannasch, 2006; Zinder and Dworkin, 2006). Some strategies and bacterial life-styles are, however, suitable to discriminate between certain subgroups within a phylum. In the following, some key features that may be confined to the respective groups are specified. The groups are assigned to phyla according to the “classical” phylogenetic scheme, obtained by

16S-rDNA sequence analysis (Cole et al., 2008; cf. Madigan et al., 2009).

Ancient phyla

Several representatives of the ancient bacterial groups clustering deep in the phylogenetic tree are hyperthermophilic, some of them are chemolithotrophs. The hyperthermophilic genus *Aquifex* is an obligately hydrogen oxidizing, microaerophilic, chemolithotrophic (see *Chemolithotrophy*) bacterium (Huber and Eder, 2006). The fixation of carbon dioxide does not depend on the Calvin cycle (ribulose biphosphate carboxylase as key enzyme), like in further derived phyla and green plants, but, instead, on a reversed citrate cycle. The organisms are not capable to grow on organic molecules, that is, they are obligate chemolithotrophs utilizing molecular hydrogen or reduced sulfur compounds as electron donors, at optimum growth temperatures of 85°C. Thus, the environmental conditions for the ecological niche of *Aquifex* are equivalent to the reducing conditions of the earth’s early atmosphere. The related genera *Hydrogenobacter* and *Thermocrinis* share most of *Aquifex*’ properties, but are aerobic and also utilize organic compounds.

Several important cellular features that are found in most bacterial phyla are already present in this ancient lineage: the cytoplasmic membrane is surrounded by another membrane of lipid bilayer type (outer membrane). Thus, the membranes enclose an additional compartment, the periplasmic space. The periplasmic space contains the rigid murein (peptidoglycan) sacculus. Another feature found in all, including the most ancient bacterial phyla is the bacterial flagellum (Figure 2a). Though analogous

Bacteria, Table 1 Groups of chemolithotrophic bacteria (After Schlegel and Jannasch, 2006, with modifications)

Typical species	Lineage	Metabolic process	Electron donor	Electron acceptor	Product
<i>Aquifex</i>	Aquificales	Hydrogen oxidation	H ₂	O ₂	H ₂ O
		Sulfur oxidation	S ₂ O ₃ ²⁻ , S ₀	O ₂	SO ₄ ²⁻
<i>Ralstonia eutropha</i>	Beta-Proteobacteria	Hydrogen oxidation	H ₂	O ₂	H ₂ O
<i>Pseudomonas carboxydovorans</i>	Gamma-Proteobacteria	CO oxidation	CO	O ₂	CO ₂
<i>Nitrosomonas europaea</i>	Beta-Proteobacteria	Ammonium oxidation	NH ₄ ⁺	O ₂	NO ₂ ⁻
<i>Nitobacter</i>	Alpha-Proteobacteria	Nitrite oxidation	CO ₂	O ₂	NO ₃ ⁻
<i>Thiobacillus thiooxidans</i>	Beta-Proteobacteria	Sulfur oxidation	H ₂ S, S ₀	O ₂	SO ₄ ²⁻
<i>Thiobacillus ferrooxidans</i>	Beta-Proteobacteria	Iron oxidation	Fe ²⁺	O ₂	Fe ³⁺
<i>Beggiatoa alba</i>	Gamma-Proteobacteria	Sulfur oxidation	H ₂ S, S ₀	O ₂ , NO ₃ ⁻	SO ₄ ²⁻ , N ₂
<i>Acetobacterium woodii</i>	Firmicutes	Acetogenesis	H ₂	CO ₂	Acetate

Bacteria, Table 2 Groups of phototrophic bacteria (After Schlegel and Jannasch, 2006, with modifications)

Bacterial group	Lineage	Key genus	Chemoorganotrophic growth	Electron donors for photosynthesis
Purple non-sulfur bacteria	Alpha-/beta-Proteobacteria	<i>Rhodospirillum</i>	+	H ₂ , organic, (S ²⁻)
Purple sulfur bacteria	Gamma-Proteobacteria	<i>Chromatium</i>	—	S ²⁻ , S ⁰ , S ₂ O ₃ ²⁻ , H ₂
Green sulfur bacteria	Chlorobi	<i>Chlorobium</i>	—	S ²⁻ , S ⁰ , S ₂ O ₃ ²⁻ , H ₂
<i>Chloroflexus</i> group	Chloroflexi	<i>Chloroflexus</i>	+	Organic (S ²⁻)
Heliobacteriaceae	Firmicutes	<i>Heliobacterium</i>	—	Organic
Aerobic phototrophic Proteobacteria	Alpha-Proteobacteria	<i>Roseobacter</i>	—	Organic
Cyanobacteria	Cyanobacteria	<i>Synechococcus</i> <i>Oscillatoria</i>	—	H ₂ O H ₂ O (S ²⁻)

Bacteria, Table 3 Bacterial groups and their electron acceptors for respiratory processes (After Schlegel and Jannasch, 2006, with modifications)

Physiological group	Typical species	Lineage	Respiratory process	Electron acceptor	Reduction products
Denitrifiers	<i>Pseudomonas denitrificans</i>	Gamma-Proteobacteria	Aerobic respiration nitrite respiration	O ₂ , NO ₃ ⁻	N ₂ , N ₂ O, NO ₂ ⁻
Sulfate reducers	<i>Desulfovibrio vulgaris</i>	Delta-Proteobacteria	Sulfate respiration	SO ₄ ²⁻	S ²⁻
Sulfur reducers	<i>Desulfuromonas acetoxidans</i>	Delta-Proteobacteria	Sulfur respiration	S ⁰	S ²⁻
Acetogenic bacteria	<i>Acetobacterium woodii</i>	Firmicutes	Carbonate respiration	CO ₂	acetate
Succinogenic bacteria	<i>Wolinella succinogenes</i>	Epsilon-Proteobacteria	Fumarate respiration	fumarate	succinate
Iron reducer	<i>Pseudomonas GS-15</i>	Gamma-Proteobacteria	Iron respiration	Fe ³⁺	Fe ²⁺

motility structures are also found in Archaea (and in Eukarya), they are phylogenetically completely unrelated. For other types of appendages (bacterial pili, Figure 2a), homologues in Archaea could be described (Szabo et al., 2007).

Thermotoga and related genera also comprise chemoorganotrophic hyperthermophilic representatives. Comparative genomics revealed that more than 20% of the *Thermotoga* genome shares strong homologies with genes from various hyperthermophilic archaeal species, accounting for an extensive inter-domain horizontal gene transfer (Nelson et al., 1999).

Chloroflexi and Chlorobi

(Bacterio)chlorophyll-dependent photosynthesis (see *Photosynthesis*) is unique for bacterial organisms (Table 2; Overmann and Garcia-Pichel, 2006). Ancestors of green nonsulfur bacteria (Chloroflexi) were very likely the first photosynthetic organisms of the bacterial domain (Oyaizu et al., 1987). The key genus *Chloroflexus* is a thermophilic representative of the group. Besides photoautotrophic growth, *Chloroflexus* is also able to use organic compounds. Carbon dioxide fixation is still Rubisco independent and is carried out by transfer of hydrogen carbonate to activated acetate and propionate

Bacteria, Table 4 Groups of fermentative bacteria

Fermentative process	Typical species	Lineage	Preferred substrates	Fermentation products (minor products)
Ethanol fermentation	<i>Zymomonas mobilis</i>	Alpha-Proteobacteria	Glucose	Ethanol (CO ₂)
Lactate fermentation – homofermentative – heterofermentative	<i>Lactobacillus casei</i> <i>Leuconostoc mesenteroides</i>	Firmicutes	Glucose, lactose Glucose, lactose	Lactate Lactate (ethanol, CO ₂)
Butyrate fermentation	<i>Clostridium butyricum</i> <i>Clostridium acetobutylicum</i> <i>Clostridium klyuveri</i>	Firmicutes Firmicutes Firmicutes	Glucose Glucose Ethanol+acetate	Butyrate (acetate, H ₂ , CO ₂) Butyrate, butanol (acetone, 2-propanol)
Homoacetate fermentation	<i>Clostridium acetivum</i>	Firmicutes	Fructose	Acetate
Propionate and succinate fermentation	<i>Propionibacterium pentosaceum</i> <i>Veillonella alcalescens</i> <i>Bacteroides ruminicola</i>	Actinobacteria Firmicutes	Sugars, Lactate Lactate Sugars	Propionate (succinate) Propionate (acetate, H ₂ , CO ₂) Propionate
Mixed acid and butanediol fermentation	<i>Escherichia coli</i> <i>Enterobacter aerogenes</i>	Gamma-Proteobacteria	Glucose, lactose Glucose	Lactate, ethanol acetate (formate, succinate, H ₂ , CO ₂) 2,3 butanediol, ethanol (formate, H ₂ , CO ₂)
Amino acid fermentation	<i>Clostridium tetanomorphum</i> <i>Clostridium sticklandii</i> <i>Clostridium oroticum</i>	Firmicutes Firmicutes Firmicutes	Glutamate Lysine Orotate	Butyrate (acetate, CO ₂ , NH ₃) Butyrate (acetate, NH ₃) Acetate (CO ₂ , NH ₃)

(acetyl-coenzyme A, propionyl-coenzyme A) in the hydroxypropionate pathway. Green sulfur bacteria (Chlorobi) represent a separate lineage of anoxygenic photosynthetic bacteria. Similar to photosynthetic Proteobacteria, the organisms use reduced sulfur compounds (H₂S, S₀) as well as organic compounds as electron donors. The organisms use a reverse citric acid cycle for carbon dioxide fixation. A remarkable structural feature, the chlorosome, consisting of densely stacked self-assembled antenna bacteriochlorophylls, is a simple but very effective light harvesting complex. This arrangement transfers light energy (excitons) effectively to the reaction centre in the cytoplasmic membrane. The organisms are, hence, adapted to very low light conditions. Chlorosome genes were transferred, by horizontal gene transfer, to some phototrophic lineages, including some genera of the *Chloroflexus* group (cf. Hanada and Pierson, 2006).

Spirochetes

Spirochetes are rather structurally than metabolically remarkable (Charon et al., 1992). The spirochete endoflagellum is of the standard bacterial type, but is located in the periplasmic space. In all other bacterial groups, the flagellum (if present) traverses all layers of the envelope. The endoflagellum is helically wound around the flexible protoplast and gives the cell its unique, helically coiled appearance. The movement of the flagellum drives the cell body in a drill-like manner. By this way, movement of the cell in highly viscous media like tissue is facilitated. In fact, numerous symbiotic and

pathogenic organisms belong to this group (*Teponema*, *Borrelia*, *Leptospira*).

Deinococcus/Thermus

Another separate lineage of extremophilic bacteria is represented by the key genera *Deinococcus* and *Thermus*. The organisms mainly oxidize carbohydrates and proteins. *Thermus* species are thermophilic and grow between 50°C and 80°C. The remarkable members of the *Deinococcus* group are adapted to desiccation and ionizing or ultraviolet radiation. The composition and thickness of the cell wall, DNA compaction, and DNA repair systems are special protective features (Da Costa et al., 2006).

Flavobacteria/Cytophaga

The Flavobacteria/Cytophaga phylum comprises diverse, mostly heterotrophic, anaerobic or aerobic bacteria (Bernardet and Nakagawa, 2006). Within this group, the members of the genus *Bacteroides* represent the dominant bacteria in the human large intestine. The second key genus *Flavobacterium* is mostly found in freshwater and marine habitats. The Acidobacteria with the genera *Acidobacterium*, *Geothrix*, and *Halophaga* are heterotrophic soil inhabitants. It is known from phylogenetic analysis of environmental DNA that uncultured members of the genera are widespread in other terrestrial and aquatic habitats and may thus play an important ecological role. Several members of *Cytophaga* and related genera are important degraders of cellulose and other polysaccharides. Cells move by gliding, a surface motility mechanism that is also observable in other bacterial lineages.

Bacteria, Figure 2 Some cytological features of bacteria. (a) The bacterial flagellum (fl) is a unique motility structure of the bacterial kingdom. The short spikelike appendages (pili) are also found in Archaea (electron micrograph of a metal shadowed *Escherichia coli* cell). (b) The corkscrew-like *Spirochete* morphology (here, *Spirochaeta thermophila*) is determined by the flagellum ("axial filament") wound around the elongate cell body. The axial filament propels the whole cell in a drill-like manner. (c) Aquatic organisms tend to form long filaments (filamentous cyanobacterium *Phormidium* sp.). Light micrograph, differential interference contrast. (d) Several filaments of the cyanobacterium *Microcoleus*, frequently found in terrestrial habitats, are surrounded by a polysaccharide sheath (green). The filaments (red) glide out of the tubelike sheath. Sheaths are found in various bacterial groups. Fluorescence light micrograph. (e) *Bacillus* mother cell with endospore. Electron micrograph of an ultrathin section. (f) Purple sulfur bacterium (*Chromatium*) with intracellular sulfur granula. Light micrograph, phase contrast.

The gliding motility of *Cytophaga* and relatives, however, is based on a unique, not yet understood, cell envelope-associated mechanism.

Planctomyces/Verrucomicrobia

The *Planctomyces/Verrucomicrobia* lineages comprise morphologically uncommon groups of uncertain phylogeny. Planctomycetes develop protein stalks as attachment structures and divide by budding (instead of binary fission, the common way of bacterial and archaeal cell division). Peptidoglycan is missing. Planctomycetes and the related phylum of Verrucomicrobia also show a highly compartmentalized cytoplasm (Lee et al., 2009). Endocytosis-like processes, a typical feature of eukaryotes, could also be observed (Lonhienne et al., 2010).

In *Gemmata* spp. the nucleoid is surrounded by an intracytoplasmic unit membrane. The anammoxosome in *Brocadia anammoxidans* is a structurally similar compartment, but appears to be involved in the compartmentation of anaerobic oxidation of ammonia, which is a unique feature of this group. The genera *Verrucomicrobium* and *Prostheco bacter* possess lobe-like cellular extensions. The organisms are mostly found in freshwater habitats. The lobed appendages increase the cell surface and facilitate the uptake of substrate molecules in an oligotrophic life-style.

Cyanobacteria

Cyanobacteria and prochlorophytes differ from all other phototrophic bacteria in fundamental ways (Overmann

and Garcia-Pichel, 2006). The oxygenic photosynthesis, conducted by cyanobacteria, requires photosystems acting over a wide redox span. To split the water molecules, the reduction potential of chlorophyll in photosystem II must be more positive than that of the O_2/H_2O couple. Excited electrons are transferred, via several redox carriers, to a second photosystem (PS I), capable of NAD(P)H regeneration. The reducing power is particularly needed for carbon dioxide fixation (for fixation of 1 mol CO_2 , 2 mol NADPH is required), carried out by the Calvin cycle. A unique feature for Cyanobacteria are phycobilins as accessory (light harvesting) pigments, an adaptation to low light conditions. Like plastids, cyanobacteria contain intracytoplasmic thylakoid membranes as additional compartments for the membrane-bound photosystems.

Cyanobacteria are the morphologically most diverse group of bacteria, with some organizational levels analogous to eukaryotic algae (Figure 2c; Waterbury, 2006). Many species are filamentous. They are present in marine and freshwater, as well as in terrestrial habitats (Figure 2c, d). Some live in symbiotic relationship to higher plants (owing to the cyanobacterial nitrogen fixing activity). Several filamentous species carry out nitrogen fixation in specialized cells (heterocysts), lacking the oxygen evolving photosystem II.

Since cyanobacteria are responsible for oxygenation of the early atmosphere, the group has left the possibly deepest impact ever on earth's ecosystems. They are still of global importance for carbon cycling. Marine species are responsible for an estimated 20–40% of carbon dioxide fixation in oceans (e.g., Campbell and Vault, 1993). Since recent Cyanobacteria and the endosymbiotic plastids of green plants have common ancestors, most of the photosynthetic processes are basically due to the activity of Cyanobacteria and their ancestors.

Firmicutes/Actinobacteria

Next related to Cyanobacteria are the Firmicutes/Actinobacteria phyla (Stackebrandt and Schumann, 2006; Madigan et al., 2009). A common feature of all species within these groups is the lack of an outer membrane. Most members of the groups are chemoheterotroph and exhibit a thick peptidoglycan layer, resulting in a positive reaction of the Gram stain. Thus, the organisms are also referred to as “Gram-positive.” The thick cell wall may be also considered as an adaptation to the high osmotic stresses in terrestrial ecosystems (i.e., soil). The genera *Bacillus* and *Clostridium*, but especially the filamentous Actinobacteria (the genus *Streptomyces*, in particular) are important groups in soil habitats. Interestingly, also a small group of photosynthetic genera belongs to the Firmicutes. *Heliobacterium* and related genera are anaerobic, photoheterotrophic soil bacteria, with a minimal photosynthetic apparatus and incapable of carbon dioxide fixation (Asao and Madigan, 2010). *Frankia* genera are important nitrogen-fixing symbionts in alder roots. The production of different antibiotic agents

is another important feature, especially in Actinobacteria and *Bacillus*. Another unique feature within this lineage is the formation of endospores (Figure 2e).

Key genera of endospore formers are *Bacillus* and *Clostridium*. Whereas bacilli are aerobic respiratory organisms, clostridia lack a respiratory chain and are obligate anaerobic, fermenting organisms. They are important for anaerobic degradation of organic compounds, mostly producing organic acids (Table 4). Several clostridia as well as related acetogenic bacteria (e.g., *Acetobacterium*, *Acetogenium*) grow anaerobically either by using carbon dioxide as the terminal electron acceptor in anaerobic respiration with hydrogen as substrate (i.e., chemolithoautotrophically), or by fermenting carbohydrates. In either case, the acetyl-CoA pathway is used to reduce carbon dioxide to acetate. In the course of carbon dioxide reduction to acetate, a sodium ion gradient (instead of a proton gradient) across the membrane is generated that drives ATP synthesis.

Lactic acid bacteria obtain energy solely by fermentative processes. They typically have limited biosynthetic abilities, and need external sources of amino acids, vitamins, purines, and pyrimidines. This life-style is an adaptation to commensalism with other organisms: lactic acid bacteria mainly live on (decaying) plant leaves and fruit, the skin surface and the intestinal mucosa of mammals. Due to their ability to produce high amounts of lactic acid from carbohydrates (including lactose), their habitats are difficult to colonize by competing microorganisms. This also excludes pathogens from mucosal tissue. Another beneficial effect is the conservation of food (especially dairy products) by lactic acid fermentation.

Interestingly, some members of the Gram-positive lineage lost their peptidoglycan layer. These cell wall-less bacteria (key genera *Mycoplasma*, *Spiroplasma*) live as parasites on animal and plant tissue. The lack of a cell wall facilitates the flow of substrates from the host to the bacterium.

Proteobacteria

The most diverse bacterial lineage, the Proteobacteria, is divided into five subdivisions (alpha, beta, gamma, delta, and epsilon). Within most subdivisions, all metabolic key processes, ranging from chemo- and photoautotrophy to chemoheterotrophy, respiration, and fermentation (Tables 1–4), are common (Kersters et al., 2006; Madigan et al., 2009). Here, just the ecologically most important life-styles are pointed out. At least in three subdivisions, photoautotrophs are present (Overmann and Garcia-Pichel, 2006). All of them carry out anoxygenic photosynthesis with one photosystem; different types of intracytoplasmic membranes (lamellar, spheroidal) can be found (Tucker et al., 2010). Electron donors are reduced sulfur compounds (such as H_2S) in purple sulfur bacteria (Figure 2f) and mostly organic compounds (H_2S also in low concentrations) in purple non-sulfur bacteria. Purple non-sulfur bacteria are photoheterotrophic

organisms that utilize external carbon sources, if available. Most of them also fix carbon dioxide by the Calvin cycle.

Chemolithoautotrophy occurs in all proteobacterial subdivisions. Interestingly, ammonia and nitrite oxidation is mainly confined to the Proteobacteria. In four subdivisions (and one additional, recently discovered lineage, related to Proteobacteria) obligate chemolithotrophic nitrifying bacteria, oxidizing either ammonia to nitrite or nitrite to nitrate are present. Like phototrophs, also nitrifying bacteria contain internal membranes. Oxidation of sulfur and iron is represented by several groups in four proteobacterial subdivisions. Sulfur-oxidizing genera have been found in four proteobacterial subdivisions. Some genera are acidiphilic (e.g., *Acidithiobacillus*, *Thiomonas*). Among sulfur oxidizing chemolithotrophs (thiotrophic bacteria), exceptionally large morphotypes were described (*Beggiatoa*, *Thioploca*, *Thiomargarita*). Several sulfur oxidizers, especially from the gamma-subgroup, live in symbiosis with marine mollusks (Dubilier et al., 2008). Oxidation of hydrogen, already mentioned for some bacterial stem lineages, is also widespread in Proteobacteria. All hydrogen oxidizers are facultative chemolithotrophs, that is, they are also able to grow on organic compounds (Kelly and Wood, 2006).

Up to now, the aerobic methanotrophy is mainly confined to Proteobacteria, though recently, a methanotrophic verrucomicrobial bacterium could be found (Chistoserdova et al., 2009). Methylotrophic bacteria oxidize a variety of C₁ compounds (methanol, methylamine, formate). All methanotrophs possess methane monooxygenase as key enzyme for hydroxylation of the chemically inert methane to methanol. Some methanotrophic bacteria are also symbionts in marine animals.

Several genera are well-known model organisms especially for medical microbiology, such as pseudomonads and enterobacteria. Both groups are chemoorganotrophic, respiratory bacteria, enteric bacteria are facultative anaerobes. In global cycles, however, these organisms are largely insignificant. Especially enteric bacteria (within the gamma-subdivision), as commensals and pathogens of diverse higher organisms are well adapted to their hosts.

Sulfate and sulfur reduction is not only restricted to Proteobacteria. *Archaeoglobus*, as an example, is an archaeon, *Thermodesulfobacterium* is a deeply branching genus close to the root of the bacterial phylogenetic tree. Most of the sulfate- and sulfur-reducers are, however, proteobacteria that belong to the delta-subdivision. They are obligate anaerobes using mainly hydrogen, fatty and other organic acids or alcohols as energy sources. Sulfate or elemental sulfur serve as the terminal electron acceptors in an anaerobic respiration with hydrogen sulfide as product. The organic compounds are either oxidized to acetate or to carbon dioxide. These organisms are geochemically important, and are widespread in anaerobic sulfate-rich environments (Barton and Fauque, 2009).

Nitrogen fixation is a feature of multiple bacterial and archaeal genera, only a few groups are important symbiotic organisms. The alpha-proteobacterial Rhizobia

conduct specific symbiosis with legume plants by formation of root nodules.

Several proteobacterial groups exhibit differentiated life cycles: filamentous beta-Proteobacteria like *Spaerotilus* form bundles of sheathed filaments in eutrophic freshwater habitats. Under unfavorable conditions, flagellated swarmer cells are liberated from the open tip of a sheath. Sheaths of *Leptothrix* are involved in the precipitation of Fe³⁺ and oxidation of Mn⁴⁺. In iron-rich waters, mass developments of iron oxide-covered sheaths form large flocculent layers, which are also involved in the formation of bog iron deposits (Crerar et al., 1979). Prosthecae bacteria are primarily found among the alpha-proteobacterial subgroup. Members of this group have many different types of extensions (prosthecae) that contain cytoplasm and are bounded by the cell wall. Similar extensions are formed by the genera *Hyphomicrobium* and *Rhodomicrobium*. Daughter cells arise as growing buds from the hyphal tips. In *Caulobacter*, a stalk attaches the cell to a surface, whereas at the distal cell pole, a flagellated swarmer cell is formed. After division, the swarmer attaches to a new place and will form a new stalk at the formerly flagellated pole (Angert, 2005). The myxobacteria have a complex life cycle, which culminates in the production of fruiting bodies containing resting structures called myxospores. The formation of these structures requires the cooperation and coordinated differentiation of large numbers of cells. Aggregates of cells form through a chemotactic response (Zusman et al., 2007).

Summary

The brief overview points out that bacteria are taxonomically as well as metabolically more diverse than Archaea. Though the phylogenetic relationships among the bacterial phyla is still a matter of debate, several lines of evolutionary developments can be stated.

Chlorophyll-dependent photosynthesis must have been developed early in bacterial evolution, though some lineages may also have acquired genes of the photosynthetic apparatus by horizontal gene transfer. Fixation of carbon dioxide is not conducted via the Calvin cycle in stem groups, but a common feature in Cyanobacteria and Proteobacteria.

Except from Firmicutes/Actinobacteria and Planctomycetes, bacterial cell envelopes consist of two double-layer membranes. It is a matter of debate, if the Firmicutes are a lineage closest to the root of the bacterial phylogenetic tree or if the membrane got lost as a secondary event. The volume enclosed by both membranes, the periplasmic space, is, especially in Proteobacteria, of significance for cellular transport, DNA transfer, and cellular motility. Intracytoplasmic membranes are widespread in Proteobacteria as well as Cyanobacteria, but have not yet been detected in the basal lineages or in Archaea.

Several major phyla contain symbiotic and pathogenic organisms, especially Firmicutes and Proteobacteria

(as far as we know, no Archaeon is pathogenic in a strict sense). Especially within the bacterial “crown group,” complex host–symbiont/pathogen interaction has been developed. Mitochondria have very likely an alpha-proteobacterial ancestor (Gray et al., 1999).

Though biofilms, as an elementary type of multicellular organization, are already found in Archaea, some true multicellular stages in bacteria exhibit elaborate cellular differentiations and complex life cycles. In aquatic habitats, the organisms sometimes switch from planktonic to sessile stages. Several groups of bacteria exhibit diverse adaptations to terrestrial habitats: Firmicutes develop extremely durable and heat-resistant endospores, streptomycetes grow and develop like zygomycete or ascomycete fungal mycelia with branched hyphae and conidia-like exospores. A similar convergence with life cycles to a eukaryote is carried out by myxobacteria. Their life cycle has some striking analogies to cellular slime molds and represents the most complex pattern of bacterial differentiation known so far.

In brief, the development of photosynthesis, the colonization of terrestrial (soil habitats), and the interaction with eukaryotic hosts, are besides the diverse metabolic capabilities, the major achievements of bacteria.

Aquatic bacteria

Definition

Bacterial component of the plankton that drifts in the water column of both seawater and freshwater ecosystems.

Introduction

The name bacterioplankton comes from the association of the Greek word *πλαγκτός* “planktós,” meaning “wanderer” or “drifter,” and bacterium, a word coined in the nineteenth century by Christian Gottfried Ehrenberg (Thurman, 1997). In contrast to land, microbes drive the ecology of the aquatic environments both as producers and consumers of fixed carbon. Their colossal biomass vastly outreaches the ones of all other members of the oceanic and freshwaters biota. Considering its size, the Ocean encompasses more bacteria than the count of known stars (estimated to 10^{21}) in the Universe. Though its role in aquatic ecosystems was for long eluded, the bacterioplankton carries out the largest fraction of the biological activity and occupies a range of ecological niches.

Enumeration and description

Since the beginning of microbiology, counting the number of bacteria that occur in various aquatic environments has been an exciting subject of investigation. Because of the size and the mobility of the bacterioplankton, early bacteriologists had difficulties to simply enumerate them with a conventional microscope. With the development of appropriate techniques (e.g., size selection on membrane filters and DNA/RNA specific fluorochromes stainings), as well as advances in microscopy, bacterioplanktonic cells could be observed and counted (Hobbie et al., 1977). This method indicated that the bacterioplankton were on an average $\sim 10^6$ cells per milliliter of water. Recent developments in flow cytometry have confirmed and sharpened these counts (Amann et al., 1990). In the water column, the bacterioplankton is also exposed to grazing activity by larger protists and viral infections, but irrespective to variations in primary productivity, these two causes of mortality seem to maintain a relatively constant abundance.

Though it is not always mentioned in the current literature, a clear distinction should be made between the fraction of the bacterioplankton that is attached to drifting particles of organic matters (also called “marine snow” in the marine environment) and the fraction that is free-living in the water column. A common trait for free-living bacterioplankton is their small size, or small cell volume, ranging from 0.1 to $0.22 \mu\text{m}^3$, which is about ten times lower than that of the most attached bacterioplankton in aquatic habitats or in soils (Fenchel et al., 1998) and the most cultured cells.

Bacterioplankton biological activity

Based on both direct observations and indirect measurements of bacterial growth rates in whole seawater (e.g., frequency of dividing cells (Hagström et al., 1979), radioactive thymidine or leucine incorporation (Fuhrman and Azam, 1982; Chin-Leo and Kirchman, 1988)) as well as when bacterial grazers (protozoans) were removed (Vacelet, 1972), generation times (i.e., the time required to double population) of most bacterioplanktons range from 0.049 to 0.080 h^{-1} .

Because a significant proportion of the bacterioplankton (99%) of the total counted cells fail to grow on nutrient-rich agar plates, it has been suggested that most counted cells were either starving cells, dormant (Stevenson and Schmidt, 1998) or even non-viable cells (Kjelleberg et al., 1987). Different in situ measurements of amino acids or glucose uptake by microautoradiography (Hoppe, 1976) indicate that from 5% to >60% of the cells are metabolically active in different aquatic environments (Tabor and Neihof, 1984; Fuhrman and Ferguson, 1986; Smith and del Giorgio, 2003). Whether or not most bacteria in aquatic environment are dormant remains controversial, most scientists will agree however that the bacterial community, as a whole and over

CLAY AUTHIGENESIS, BACTERIAL

Kurt O. Konhauser
 University of Alberta, Edmonton, Alberta, Canada

Definition

The formation of clay minerals in situ through the direct or indirect action of bacteria.

Overview

Clays are one of the largest and most diverse assemblage of minerals known. The vast majority of clay minerals are aluminum silicate in composition, with various other cations substituted into the crystal lattice. The replacement of either Si or Al can lead to an excess of negative charge, which is either neutralized by the adsorption of additional cations onto the outer mineral surfaces or within the interlayer spaces.

Within the past 2 decades, field studies have led to the general recognition that bacteria can mediate the formation of clay minerals. Some clays form as replacement products from the alteration of primary minerals. In this regard, the bacterial community growing on the rock surface potentially function initially as the weathering agents (through the production of organic acids or ligands that facilitate mineral dissolution) and later as reactive surfaces for the nucleation of secondary clay phases. For instance, Konhauser et al. (2002) documented that highly altered rocks found within active steam vents at Kilauea Volcano, Hawaii, contained bacteria with small (<500 nm in diameter) grains of smectite $[(\text{Al}_{1.6}\text{Fe}_{0.4})(\text{Si}_{3.8}\text{Al}_{0.2})\text{O}_{10}(\text{OH})_2\cdot\text{K}_{0.2}]$ attached directly to the outer cell walls.

Many of the elements now incorporated into the clays originated when the volcanic glass dissolved and released them into the pore waters. Leveille et al. (2002) similarly documented the formation of kerolite $[\text{Mg}_3\text{Si}_4\text{O}_{10}(\text{OH})_2 \cdot n\text{H}_2\text{O}]$ in association with microbial mats colonizing the surfaces of walls and ceilings within basaltic sea caves on the north coast of Kauai, Hawaii. That microorganisms were in some way involved in mineral formation was suggested by the lack of kerolite within basalt vesicles near the rock surface or in the carbonate-rich evaporitic coatings found on other exposed surfaces without the presence of microbial mats.

Other clays form in environments far removed from the actual sites of weathering. The best examples come from biofilms retrieved from the sediment–water interface of lakes and rivers. Ferris et al. (1987) initially described complex (Fe,Al)-silicates on bacterial cells growing in metal-contaminated lake sediment in northern Ontario. These precipitates ranged from poorly ordered and uncharacterized phases to crystalline forms of the Fe-rich chlorite, chamosite $[(\text{Fe})_3(\text{Si}_3\text{Al})\text{O}_{10}(\text{OH})_2]$. Since then, similar clayey precipitates have been reported from various rivers around the world (e.g., Konhauser et al., 1998). What is particularly remarkable about bacterially mediated clays is that they share a number of properties, irrespective of the chemical composition of the waters from which they were sampled: (1) They are generally amorphous to poorly ordered structures. (2) All have grains sized $<1\text{ }\mu\text{m}$, although the majority are $<100\text{ nm}$. (3) The grains have a composition dominated by iron, silicon, and aluminium in varying amounts.

Based on the observations from natural studies, a general sequence of events leading to clay biomineralization can be adduced (Konhauser and Urrutia, 1999). In the initial stages, a bacterium adsorbs any number of different free aqueous iron species, i.e., Fe^{2+} , Fe^{3+} , $\text{Fe}(\text{OH})^{2+}$, and $\text{Fe}(\text{OH})_2^+$, depending on solution chemistry and redox potential. Adsorption can occur on either the cell wall,

which is frequently lined with anionic carboxyl and phosphate functional groups, or to the more neutrally charged carbohydrate-rich extracellular layers that surround the cell, including sheaths and capsules – the latter are the organic components that make up the bulk of biofilms. If the soluble iron concentration around the cell surface exceeds the solubility product of ferric hydroxide, then the reaction between the bound iron with dissolved iron will lead to the development of small ($\sim 100\text{ nm}$ in diameter), dense, mineral aggregates on the outer cell surface (Figure 1a). Indeed, it has been shown experimentally that a continuum exists between cationic iron sorption and precipitation reactions at bacterial surfaces; with the three stages of (1) sorption, (2) surface site saturation and (3) precipitation, all evident in Langmuir-type isotherms relating the solid-phase concentration of Fe(III) to the equilibrium proton and soluble Fe(III) concentrations (Warren and Ferris, 1998). Alternatively, bacteria can attract preformed nanometer-sized ferric hydroxide particles from suspension (Glasauer et al., 2001), thereby negating the need for the nucleation step. In most solutions, iron is only found in trace amounts compared to other ions, particularly silica. Under those conditions, the adsorbed/particulate iron may instead serve as kinetically favorable site for the development of more complex precipitates of variable clay composition, morphology, and structure (Figure 1b).

Why these clays form is likely as follows. In the pH range of most natural water bodies, negatively charged counter-ions, or those molecules that are neutrally charged but exhibit residual surface electronegativity (e.g., oligomeric and colloidal silica species), accumulate near the solution-adsorbed iron/solid interface to neutralize the net positive charge of iron. Two surface species of iron oxide exist in this pH range; FeOH_2^+ and $\text{Fe}(\text{OH})^0$, but the majority of the surface charge is positive at circumneutral pH. The initial (Fe,Al)-silicate phases then form via hydrogen bonding between the hydroxyl groups

Clay Authigenesis, Bacterial, Figure 1 Transmission electron micrographs (TEM) of bacteria (stained) from the Rio Solimões in Brazil. associated with the cell-bound iron and the hydroxyl groups in the dissolved silica, aluminum, or aluminosilicate complexes (e.g., Taylor et al., 1997; Davis et al., 2002). Exactly how these reactions occur in nature has not been ascertained, but we do know that dimeric silica (the species that accounts for more than 99% of the oligomeric silica in natural waters) is highly reactive toward iron hydroxide surfaces (Reaction 1), and that oligomeric silica exhibits a strong affinity for dissolved aluminum, forming soluble hydroxy-aluminosilicate ions (e.g., Reaction 2) that subsequently react with cell-bound iron.

This arrangement of ions forms an electric double layer with iron attaching to the bacterial surface as an inner sphere complex, while the silica-aluminosilicate species attach as more diffuse outer layers. The surface charge of these composites is inevitably dependent upon the solution pH, the ionic strength of the solution, and the time of reaction, such that as the particles age more silica (and aluminium) sorb. Interestingly, this mechanism of binding Fe to the bacterial cell surface and subsequent reaction with Si and Al from solution has been shown in experimental systems with *Bacillus subtilis* (e.g., Urrutia and Beveridge, 1994). Accordingly, if the microbial mats are subject to sufficiently concentrated solutions, then continued reaction of the dissolved components to the Fe-bearing solid interface eventually results in the formation of amorphous to poorly ordered clay phases. Often, these reactions lead to the partial and complete encrustation of some bacterial cells as abiological surface reactions accelerate the rate of mineral precipitation: in some biofilms, the density of clayey material surrounding individual cells can extend hundreds of nanometers away from the cell surface (Figure 2). Over time, these hydrous compounds dehydrate, some converting to more stable crystalline forms. This latter material presumably uses some fraction of the precursor surface as a template for its own growth, in effect circumventing the need for direct nucleation (Steeff and van Cappellen, 1990). Once it begins to grow, the more stable clay phase increases its own surface area until it can control the composition of the proximal solution. When this happens, the saturation state of the solution moves below the solubility of the precursor, inhibiting further growth, or even dissolving the precursor.

The reactions above are naturally an oversimplification because a number of inorganic processes are also at play. It is well known that soluble Al–Si complexes precipitate as poorly ordered Al–silicates when a state of supersaturation is achieved (Wada and Wada, 1980). Moreover, Fe ions can readily be incorporated into those structures

Clay Authigenesis, Bacterial, Figure 2 TEM image of highly encrusted bacterium from the Speed River in Ontario, with clay minerals extending over 500 nm away from cell surface. Arrow indicates surrounding capsule in which the clay minerals have formed. Scale bar = 500 nm.

leading to clay-like products (Farmer et al., 1991). All these reactions can conceivably take place in the proximity of bacterial surfaces or within the extensive EPS, particularly since diffusion through the polysaccharide matrix is inherently slow, and a microenvironment can be established that is conducive to mineralization. Additionally, colloidal species of (Fe, Al)-silicate composition that either form initially in the water column or are products of weathering and soil formation, may react directly with the outermost cellular layers. It follows that anything which will neutralize or diminish the charge of the colloids (e.g., bacterial surface if colloids are positively charged or adsorbed iron if the colloids are negatively charged) will cause the particles to flocculate out of solution.

One of the intriguing questions that arises from the observation of bacterial cells completely encrusted in clays is why do they allow for mineralization to occur? It has been established that bacteria have the ability to partially control their surface charge (Doyle, 1989). During metabolism, a membrane-induced proton motive force continuously pumps protons into the wall fabric that effectively compete with metal ions for anionic wall sites (Urrutia et al., 1992). Subsequently, living bacteria may be able to reduce authigenic mineral formation (and detrital mineral adhesion) on their cellular surfaces, unless environmental conditions exceed their capacity to compensate. In most aqueous environments with low dissolved solutes, this condition should not arise. Therefore, the presence of epicellular minerals on bacteria suggests that (1) the cells observed under the electron microscope had lysed prior to mineralization, or (2) that the mineralized matrix is in some way advantageous to the microorganism. Several possibilities for the latter

exist. First, clays provide a good source of exchangeable inorganic nutrients readily available to microbes (Tazaki et al., 1994). Second, clays such as montmorillonite stimulate the respiration of bacteria by maintaining the pH and water content of the environment at a level suitable for growth (Stotzky and Rem, 1966). Third, the formation of an external mineralized matrix may protect the living cells from the detrimental effects of toxin-producing microorganisms (Habte and Barrion, 1984) and predation by grazing protozoans (e.g., Heynen et al., 1988).

Summary

Microorganisms are commonly associated with fine-grained (Fe, Al)-silicates of variable composition. The inorganic phases develop in a predictable manner, beginning with the adsorption of cationic iron to anionic cellular surfaces, supersaturation of the proximal fluid with Fe (III), nucleation and precipitation of a precursor ferric hydroxide phase on the cell surface, followed by reaction with dissolved silica and aluminium, and eventually the growth of an amorphous clay-like phase.

COCCOLITHOPHORES

Volker Thiel

University of Göttingen, Göttingen, Germany

Coccolithophores (coccolithophorids) are a group of unicellular, marine, planktonic algae belonging to the haptophytes (Prymnesiophyta). The coccolithophores are capable of controlling the intracellular precipitation of calcite onto organic plates and the assembly of the mature carbonate scales at the cell surface. These scales, the coccoliths, are spherical or oval, often intricately patterned and generally less than 20 µm in diameter. Given the abundance of coccoliths in sediments, coccolithophorids have been playing a major role in the global carbon budget. They were very abundant in the Mesozoic era, particularly in the Cretaceous period, in which they became a major component of the “Chalk” lithology (e.g., White Cliffs of Dover, England). Today, coccolithophorids are accounting for about a third of the total marine CaCO_3 production, and coccoliths are a major component of the

Aquatic bacteria

Definition

Bacterial component of the plankton that drifts in the water column of both seawater and freshwater ecosystems.

Introduction

The name bacterioplankton comes from the association of the Greek word *πλαγκτός* “planktós,” meaning “wanderer” or “drifter,” and bacterium, a word coined in the nineteenth century by Christian Gottfried Ehrenberg (Thurman, 1997). In contrast to land, microbes drive the ecology of the aquatic environments both as producers and consumers of fixed carbon. Their colossal biomass vastly outreaches the ones of all other members of the oceanic and freshwaters biota. Considering its size, the Ocean encompasses more bacteria than the count of known stars (estimated to 10^{21}) in the Universe. Though its role in aquatic ecosystems was for long eluded, the bacterioplankton carries out the largest fraction of the biological activity and occupies a range of ecological niches.

Enumeration and description

Since the beginning of microbiology, counting the number of bacteria that occur in various aquatic environments has been an exciting subject of investigation. Because of the size and the mobility of the bacterioplankton, early bacteriologists had difficulties to simply enumerate them with a conventional microscope. With the development of appropriate techniques (e.g., size selection on membrane filters and DNA/RNA specific fluorochromes stainings), as well as advances in microscopy, bacterioplanktonic cells could be observed and counted (Hobbie et al., 1977). This method indicated that the bacterioplankton were on an average $\sim 10^6$ cells per milliliter of water. Recent developments in flow cytometry have confirmed and sharpened these counts (Amann et al., 1990). In the water column, the bacterioplankton is also exposed to grazing activity by larger protists and viral infections, but irrespective to variations in primary productivity, these two causes of mortality seem to maintain a relatively constant abundance.

Though it is not always mentioned in the current literature, a clear distinction should be made between the fraction of the bacterioplankton that is attached to drifting particles of organic matters (also called “marine snow” in the marine environment) and the fraction that is free-living in the water column. A common trait for free-living bacterioplankton is their small size, or small cell volume, ranging from 0.1 to $0.22 \mu\text{m}^3$, which is about ten times lower than that of the most attached bacterioplankton in aquatic habitats or in soils (Fenchel et al., 1998) and the most cultured cells.

Bacterioplankton biological activity

Based on both direct observations and indirect measurements of bacterial growth rates in whole seawater (e.g., frequency of dividing cells (Hagström et al., 1979), radioactive thymidine or leucine incorporation (Fuhrman and Azam, 1982; Chin-Leo and Kirchman, 1988)) as well as when bacterial grazers (protozoans) were removed (Vacelet, 1972), generation times (i.e., the time required to double population) of most bacterioplanktons range from 0.049 to 0.080 h^{-1} .

Because a significant proportion of the bacterioplankton (99%) of the total counted cells fail to grow on nutrient-rich agar plates, it has been suggested that most counted cells were either starving cells, dormant (Stevenson and Schmidt, 1998) or even non-viable cells (Kjelleberg et al., 1987). Different in situ measurements of amino acids or glucose uptake by microautoradiography (Hoppe, 1976) indicate that from 5% to >60% of the cells are metabolically active in different aquatic environments (Tabor and Neihof, 1984; Fuhrman and Ferguson, 1986; Smith and del Giorgio, 2003). Whether or not most bacteria in aquatic environment are dormant remains controversial, most scientists will agree however that the bacterial community, as a whole and over

long period of time, plays a paramount role in global biochemical processes.

The blue-green algae, or *Cyanobacteria*, are the “plants” of the bacterioplankton and carry out photosynthesis, which supports the entire ocean food web. In the open ocean, these phototrophic bacteria are responsible for about 80% of the total oceanic primary production, which represents about half of the planet’s primary production (ranging from 35 to 65 Gt of carbon per year) (del Giorgio and Duarte, 2002). Moreover, a new type of phototrophy has recently been discovered among marine bacterioplankton that carry bacteriorhodopsin molecules, which scavenge light to create an energetic gradient of protons (Beja et al., 2001). Since ~13% of the bacterioplankton cells in the photic zone may carry out proteorhodopsin-based phototrophy (Sabeji et al., 2005), this metabolism surely has a global significance and may be the foremost future investigation field in aquatic microbiology.

However in numbers, marine bacterioplankton are considered mostly heterotrophs, or more precisely saprotrophs, and obtain energy by consuming dissolved organic matter (DOM) released by larger aquatic animals (Smith et al., 1992) or by phytoplankton exudation (Larsson and Hagström, 1979). This activity, known as the “microbial loop” (Azam et al., 1983), is crucial to the aquatic trophic foodwebs because essential inorganic nutrients are recycled through bacterial metabolism into the water column.

Heterotrophic and phototrophic bacterioplankton are continuously grazed by protozoans (i.e., mostly flagellates and ciliates), which are later consumed by larger zooplankton, which are subsequently consumed by fishes. Phages (i.e., viruses infecting bacteria) also affect DOM turnover by lysing cells, which releases organic matter available to surrounding bacterioplankton cells (Proctor and Fuhrman, 1990).

A large fraction of the carbon flow in the aquatic ecosystem is processed by heterotrophic bacterioplankton that respire particulate and dissolved organic carbon (DOC) (del Giorgio and Duarte, 2002). Especially with the rapid increase in global atmospheric CO₂ due to modern human activities, this bacterial process is recognized as a key component in global climate regulation (Falkowski et al., 2000).

Bacterioplankton diversity and global distribution

While growth on agar plates, microscopic observations were intensively used to delineate several types of bacteria, their capacity of differentiation showed quickly to be too restrictive and new methods were required to distinguish between two species with similar cell and colony morphologies. Moreover, a general concern grew among microbiologists when they realized that many bacteria counted under the microscope could not be cultivated on agar plate or in liquid media. For instance, marine microbiologists estimated that only 1% of the cells counted

under the microscope formed colonies on agar plates, and named this issue the “Great plate count anomaly” (Jannasch and Jones, 1959; Kogure et al., 1979).

In the early 1980s, a breakthrough in bacterial taxonomy was achieved by Woese et al., who utilized ribosomal ribonucleic acids (rRNA) to catalogue related bacterial species (Fox et al., 1980; Woese et al., 1985, 1987). Applying this approach to aquatic environmental samples often recovers members from about 18 bacterial clades, mostly represented within the α -*Proteobacteria* and γ -*Proteobacteria* phyla. Moreover, members from the *Cyanobacteria*, *Actinobacteria*, *Bacteroidetes*, *Planctobacteria*, *Fibrobacter*, *Chloroflexi* and β -*Proteobacteria* are often retrieved from environmental rRNA genes clone libraries. Interestingly, though some members of the global bacterioplankton community (e.g., the so-called SAR11 clade) are recurrently found in environmental samples, and therefore show a ubiquitous distribution, endemism of rRNA genes is the most common trait of the bacterioplankton, and their diversity follows a latitudinal gradient as observed in the other macro-organisms (Pommier et al., 2007).

The extensive use of the SSU rRNA as phylogenetic marker has actually reached the level where variations in the bacterioplankton composition can be linked to observed changes both in natural (Acinas et al., 1999; Cottrell and Kirchman, 2000; Hollibaugh et al., 2002) and reconstructed environments (i.e., meso- or microcosms) (Riemann et al., 2000). The current view of marine bacterioplankton phylogeny is however being questioned together with the relevance of the SSU rRNA gene to delineate bacterial species.

Conclusions

Though it was for long considered a mass of dormant cells, bacterioplankton has proven to be a key actor in aquatic ecosystems throughout the world. As for many ecosystems, the bacterioplankton drives the whole biological activity of the water foodweb and occupies a huge variety of niches throughout the water column. Further research aims to show the importance of local bacterioplanktonic processes involved in global biogeochemistry.

Summary

The bacterial component of the plankton that drifts in the water column of all aquatic ecosystems is named *Bacterioplankton*. Though it was for long considered solely dormant, this part of the biota is now recognized as a determinant actor on the global recycling of nutrients and at the basis of all aquatic foodwebs. With a million cells per millimeter of water, they represent the most successful organisms, as well as the most diverse biome on our planet. Modern approaches combining molecular biology to epi-fluorescence microscopy have sharpened our knowledge on the abundances, the diversity and the ecology of the bacterioplankton.

Synonyms

BIFs

Definition

Sedimentary deposits of alternating iron-rich (~20–40% Fe) and iron-poor, siliceous (~40–50% SiO₂) mineral layers that primarily precipitated throughout much of the late Archean (2.7–2.5 Ga) and Paleoproterozoic (2.5–1.8 Ga), but then remerged in the Neoproterozoic (~0.8 Ga).

BIF characterization, mineralogy, and distribution

BIFs are globally distributed, with some of the larger formations being those of the Hamersley range in Australia and the Transvaal Supergroup in South Africa (Figures 1 and 2). Other major BIFs include Krivoy Rog Supergroup, Ukraine (2.2 Ga); Labrador Trough, Canada; Lake Superior Region, USA; Gunflint and Biwabik, North America

(2.2–2.0 Ga), Carajás Formation (2.6 Ga) and Urucum Region, Brazil (0.8 Ga).

The mineralogy of the least metamorphosed BIFs consists of chert, magnetite, hematite, carbonates (siderite and dolomite–ankerite), greenalite, stilpnomelane, and riebeckite (Klein, 2005): the presence of both ferric and ferrous minerals gives BIF an average oxidation state of Fe^{2.4+} (Klein and Beukes, 1992). It is generally agreed that none of the minerals in BIF are primary, but that instead, the minerals reflect both diagenetic and metamorphic overprinting. For instance, the primary iron minerals were most likely ferric hydroxide (Fe(OH)₃), greenalite ((Fe)₃Si₂O₅(OH)₄), and siderite (FeCO₃) (Klein, 2005).

Based on their depositional environment, BIFs have been categorized as Algoma or Superior type. Algoma type BIFs are generally small in lateral extent and display a volcanic association (Gross, 1965, 1980; Huston and Logan, 2004), while Superior type BIFs are found in shelf environments, are vast, and are without a dominant volcanic influence. The “Superior” type BIFs, including those in the Hamersley Group, Western Australia and the Transvaal Supergroup, South Africa, are hundreds of meters thick, over 10⁵ km² in areal extent, and contain >10¹³ t of iron (Trendall, 2002). They are characteristically laminated, with alternating Fe-rich and Si-rich layers (Figures 2 and 3). Banding can be observed on a wide range of scales, from coarse macrobands (meters in thickness) to mesobands (centimeter-thick units) to millimeter and sub-millimeter layers (Trendall and Blockely, 1970). Among the latter is the wide variety of varve-like repetitive laminae, known as microbands.

BIFs have also been categorized according to their Fe oxide composition, as hematite or magnetite BIFs (Figure 3) (James, 1954). The former refers to BIFs facies consisting principally or entirely of interbedded chert and (primary) hematite, which are in some places oolitic (e.g., the Gunflint range). The latter describes Fe oxide layers of magnetite that may grade imperceptibly into silicate rock in some areas, be mixed with carbonate, or sprinkled with hematite or chert lenses (James, 1954).

A third categorization of BIF is based on the granular versus nongranular nature of the silica layers. Granules, seen in the 2.0 Gyr Gunflint BIF are approximately 0.5 mm in diameter, irregular, and can be within a chert matrix. They can have a greenalite or magnetite core. These granules, however, do not show the concentric layering seen in hematitic oolites. Non-granular BIFs are typically thin-bedded or laminated and may chiefly be composed of minnesotaite with magnetite and carbonate in some layers (James, 1954).

Banded iron formations and the study of the early Earth

The height of BIF deposition was 2.7–2.4 Ga (Trendall, 2002; Klein, 2005), a timeframe which overlaps with the currently estimated age for the rise of oxygen on the Earth ~2.5 Ga (Anbar et al., 2007). As it is agreed that the

source of iron for these deposits was Fe(II), the Fe(III) minerals in BIF indicate that an oxidizing mechanism was present. Once oxygen began its rise due to the advent of cyanobacteria, it is plausible that an oxic mechanism formed BIF, perhaps even in pockets or oxygen oases. In the case of BIF dated prior to 2.7 Ga, however, an anoxic oxidizing mechanism is required to explain the formation of these vast deposits. The latest BIFs (0.8 Ga), which seem to represent a revival later in the geologic record, may be archives of major climate changes related to the Snowball Earth (Kirschvink, 1992; Kopp et al., 2005). Due to the intricacies of the depositional mechanisms, BIFs have been studied for decades regarding their potential as archives of the early Earth environment, but may also prove to be a detailed record of the early Earth biosphere.

BIF deposition

Depositional setting

Early studies of BIF mineral association (James, 1954), as well as comparative BIFs studies (Trendall, 1968; Beukes, 1973; Gole and Klein, 1981; Simonson, 1985; to name a few) postulated that these sedimentary deposits likely formed on the margins of cratons in semi-restricted, marine basins with minimal wave action (for a comprehensive review, Klein, 2005). They also laid a foundation for both theoretical and experimental geochemical modeling based on atmospheric (oxygen and carbon dioxide) and oceanic (iron and silica) concentrations, which are largely linked to mineralogical, petrologic, and isotopic analyses and have been invoked to describe the BIF deposition mechanism (Drever, 1974; Cairns-Smith, 1978; Han, 1978; Braterman et al., 1983; Baur et al., 1985; Francois, 1986; Garrels, 1987; Morris, 1993).

There is ample evidence that the dominant source of Fe (II) into the Archean ocean was hydrothermal (e.g., Jacobsen and Pimentel-Klose, 1988; Bau and Möller,

1993), but it has also recently been suggested that a significant fraction of the Fe in Archean seawater came from the continents (Alexander et al., 2008). The proximity of the Fe(II) source to the site of deposition, however, is still unclear. The estimated Fe(II) concentration for these basins ranges from 0.02 to 0.5 mM (Holland, 1973; Morris, 1993). This Fe(II) may have been delivered from the deep ocean to the outer continental shelf by upwelling currents from a mid-ocean ridge system (e.g., Holland, 1973). Accordingly, BIFs would sediment from below the wave base (free of wave- and storm-induced currents) onto partially submerged platforms of the continental shelves. Alternatively, Fe(II) could have been directly supplied from plumes in a seamount type system (Isley, 1995), which would curtail the difficulties introduced by the high upwelling rates required in the continental shelf model. After deposition, these sediments would undergo diagenesis, with some BIF sediment possibly even being redistributed to deeper waters via turbidity currents (Krapež et al., 2003).

There is significant evidence that Archean oceans also contained elevated concentrations of dissolved silica, possibly even to saturation with respect to amorphous silica (~2.20 mM; Siever, 1992; Maliva et al., 2005). Under such silica-rich conditions, the direct precipitation of amorphous silica could have taken place directly from the water column onto the sea basin floor (Krapež et al., 2003). Moreover, silica could have reacted with dissolved Fe(II) and precipitated as ferrous or ferric-silicates (Konhauser et al., 2007).

Theories of Precambrian BIF deposition

BIF mineralogy dictates that some form of Fe(II) oxidation was necessary for their formation, yet which mechanism(s) dominated is still highly uncertain (Figure 4). While dissolved Fe(II) readily oxidizes in the presence of oxygen at circumneutral pH, to the rise of oxygen on Earth occurred approximately 2.5 Ga (Kopp et al., 2005; Anbar et al., 2007). An alternative, O₂-independent

Banded Iron Formations, Figure 4 Models of banded iron formation deposition: The traditional model of BIF deposition involves the production of oxygen by cyanobacteria, which is released into the water column to chemically react with hydrothermal dissolved $\text{Fe}(\text{II})$ (a). The two proposed mechanisms of deposition in an anoxic ocean water column are the abiotic $\text{Fe}(\text{II})$ photooxidation by UV light, which has recently been discounted (Konhauser et al., 2007) (b), and direct microbial $\text{Fe}(\text{II})$ oxidation via anoxygenic $\text{Fe}(\text{II})$ -oxidizing phototrophy (c).

mechanism is therefore necessary to explain the deposition of the earliest BIF.

Both abiotic and biotic mechanisms of BIF deposition have been put forth. The potential role of microorganisms in BIF was first proposed 4 decades ago (Cloud, 1968) and in part addressed the difficulties in explaining these deposits based on geochemical processes alone (Brown et al., 1995). Yet, BIFs contain very little or no organic carbon (0.5% [w/w], Beukes and Klein, 1992) which makes it difficult to constrain the responsible microbial process

simply based on geochemical and petrographic studies. Any fossil information about the presence of life in the Archean has therefore been garnered from contemporaneous formations. For this reason, isotopic, biomarker, and ecophysiological studies with modern analogues have been implemented in order to supplement the geochemical BIF data and test the plausibility of the depositional models and the role of microorganisms.

Oxygenic photosynthesis model

The traditional model of BIF deposition was first postulated by Cloud (1968). Herein, $\text{Fe}(\text{II})$ is abiotically oxidized by photosynthetically produced O_2 , allowing for the indirect biogenic precipitation of ferric hydroxide as shown in Equation 1 (Figure 4a). Under an anoxic atmosphere, this O_2 could have been confined to local “oxygen oases” associated with cyanobacterial blooms in coastal settings (Cloud, 1965, 1973). Cloud (1965, 1973) further proposed that such primitive O_2 -producing photosynthetic bacteria, which lacked suitably advanced oxygen-mediating enzymes, required ferrous iron to detoxify oxygen. If so, these microorganisms would have flourished specifically when $\text{Fe}(\text{II})$ and nutrients were made episodically available. Once oxygen was present, aerobic $\text{Fe}(\text{II})$ oxidizers could also have contributed to biogenic Fe minerals precipitation (Holm, 1989).

The oldest evidence to support the presence of cyanobacteria during the time of BIF deposition came from the 3.45 billion-year-old Apex cherts, Warrawoona, Australia (Schopf, 1993). These findings, however, have since been challenged by Brasier et al. (2002) as being secondary artefacts formed by Fischer–Tropsch type reactions associated with seafloor hydrothermal systems. In fact, Buick (1988) maintained that the chert matrix of the “oldest microfossils” is a secondary hydrothermal deposit of younger age that cross-cuts the primary bedding. The use of kerogen as a marker of past life in these formations has also been challenged by experiments demonstrating the abiotic pathways of kerogen synthesis; simple organic hydrocarbons of abiological origins (e.g., formaldehyde) readily condense onto silica–carbonate inorganic filaments, and subsequently polymerize under gentle heating to yield kerogenous products (García-Ruiz et al., 2003).

In light of these studies, stronger evidence for the presence of cyanobacteria comes from the stromatolitic assemblages of the 2.7 Gyr Tumbiana Formation, Western Australia. The presence of oxygenic photosynthesis in these formations is based on their likely habitat in sulfate-deficient evaporative lakes (Buick, 1992). This is further supported by the earliest undisputed fossil assemblages of the 2.6 Gyr Campbell Group, South Africa, that include cyanobacterial genera which helped form stromatolitic reefs in shallow subtidal to intertidal settings (Altermann and Schopf, 1995).

Biomarkers, organic compounds derived from more complex precursors which still resemble the original biological molecule after a long burial history, may be used to identify a specific group of organisms in ancient rock. For example, 2 α -methylhopanes are derivatives of prominent lipids in cyanobacteria (methylbacteriohopanepolyols). Abundant amounts were extracted from bitumens of the 2.6 Gyr Marra Mamba Iron Formation and the 2.5 Gyr Mt. McRae Shale of the Hamersley Group, Western Australia (Brocks et al., 1999; Summons et al., 1999). As these compounds were first solely found in cyanobacteria, their presence was first interpreted as diagnostic of oxygenic photosynthesis, however, they have recently been detected in anoxygenic phototrophs (Rashby et al., 2007), which weakens the use of this biomarker as conclusive proof of oxygenic photosynthesis in ancient rock.

Specific steranes are more indicative of this metabolism. These are 28- to 30-carbon isomers and are unique alteration products of sterols known from extant eukaryotic cell membranes. The only prokaryotes known to synthesize sterols have biosynthetic pathways leading to different structural isomers. Importantly, O₂ is required for the biosynthesis of sterols, hence, their extraction from Archean rock suggests that at least some dissolved oxygen (~ 0.002 ml O₂ L⁻¹) was present at the time of their production (Runnegar, 1991). To date, there is no experimental evidence to support the alternative theory that steranes may have been produced via an anaerobic pathway utilizing hydrogen peroxide or organic peroxides (Fischer and Pearson, 2007), which make them a specific biomarker of oxygenic photosynthesis. They are found, for example, in the 2.7 billion-years-old shales of the Jeerinah Formation, Hamersley Group (Brocks et al., 1999). Their presence in these shales is particularly intriguing as other redox-sensitive proxies suggest that oxygen arose much later in earth history (Rye and Holland, 1998; Rasmussen and Buick, 1999; Farquhar et al., 2000). Only the presence of localized oxygen oases can explain these conflicting results.

UV photooxidation model

Prior to the rise of atmospheric oxygen and the development of a protective ozone layer, the Earth's surface was also subjected to high levels of ultraviolet radiation. This led to a theory of BIF deposition in which UV radiation drives an abiotic mechanism of Fe²⁺ oxidation and Fe(III) mineral precipitation. Specifically, under conditions of anoxia and high dissolved Fe(II) concentrations, dissolved ferrous iron species, such as Fe²⁺ or Fe(OH)⁺, can absorb radiation in the 200–400 nm range. Dissolved ferric iron is formed (Equation 2), which hydrolyzes to form ferric hydroxide at circumneutral pH (Cairns-Smith, 1978; Braterman et al., 1983) (Figure 4b).

These experiments, however, were recently carried out in complex solution simulating disequilibrium Precambrian ocean water chemistry in which Fe(II)-rich hydrothermal waters react with ambient Si-saturated seawater also containing high HCO₃⁻ concentrations (Konhauser et al., 2007). It was shown that the oxidation effects of either UVA or UVC were negligible in fluids with high dissolved Fe(II), Si, and HCO₃⁻, compared to the precipitation of ferrous-iron-silicates and ferrous carbonate. This suggests that under such conditions Fe²⁺ would have been largely deposited as Fe(II) minerals instead of being oxidized by UV radiation. The fact that Fe(III) minerals are present in BIF therefore suggests that in the absence of O₂ the alternative anoxic depositional mechanism, Fe(II) oxidation by anoxygenic phototrophs, drove Fe oxide deposition.

Anoxygenic Fe(II)-oxidizing phototroph model

Anoxygenic photosynthesis was first suggested as a BIF deposition mechanism by Garrels et al. (1973) and Hartman (1984). They proposed that light, not O₂, may have coupled the carbon and iron cycles via photosynthesis that used Fe(II) rather than H₂O as an electron donor and produced Fe(III) rather than O₂ (Figure 2c). It was only 2 decades later that the plausibility of this theory was validated by the discovery of a modern Fe(II)-oxidizing phototroph (Widdel et al., 1993). Seven extant strains of anoxygenic Fe(II)-oxidizing phototrophs are now known to use light energy to catalyze the oxidation of Fe(II) and the corresponding reduction of CO₂, which yields biomass and ferric hydroxide as shown in Equation 3.

In the context of BIFs, anoxygenic Fe(II)-oxidizing photosynthesis (photoferrotrophy) is the only direct biological process that can precipitate Fe(III) minerals in the absence of oxygen.

While no direct evidence exists for the presence of these strains on the Archean Earth, various lines of evidence support the plausibility of anoxygenic phototrophs in BIF deposition. Ecophysiological studies performed with modern anoxygenic Fe(II)-oxidizing phototrophs test the plausibility of this deposition mechanism. It was shown that these strains inhabit a wide range of growth environments; being globally distributed and present in fresh and marine waters (Ehrenreich and Widdel, 1994; Heising et al., 1999; Straub et al., 1999; Croal et al., 2004; Jiao et al., 2005). These organisms do not have a unique form, all being rod-shaped (Figure 5), yet morphological variety is apparent, one example being the presence of vacuoles in one strain, *Thiodictyon* sp. strain F4 (Croal et al., 2004). These strains also utilize a variety of substrates, such as acetate, FeS and H₂, which suggests that they are versatile enough to be an integral group in both

Banded Iron Formations, Figure 5 Anoxic Fe(II)-oxidizing phototrophs "*Rhodobacter ferrooxidans*" sp. strain SW2 (a, b) and *Chlorobium ferrooxidans* sp. strain KoFox (c) form aggregates with the Fe(III) hydroxides produced by their metabolism. Many cells are not encrusted by, but only associated with, the Fe(III) minerals that may have been the primary minerals in BIFs.

ancient and modern environments. Modeling of the photo-synthetic Fe(II) oxidation rates determined in these studies suggest that such microorganisms could have accounted for all of the Fe(III) initially deposited in primary BIF sediment (Kappler et al., 2005). Importantly, while the Fe(II) oxidation rate of these strains is dependent on light intensity, anoxygenic phototrophs can oxidize Fe(II) in light regimes befitting the photic zone of ocean water (of a few hundred meters depth) (Kappler et al., 2005). Also, Fe(II) oxidation is not hindered by high concentrations of dissolved silica (tested at 2 mM Archean ocean concentration) (Siever, 1992; Konhauser et al., 2007).

While modern studies show that cyanobacteria are indeed important in stromatolite building through the trapping and binding of carbonate grains in their filaments and extracellular polymers, several anaerobic pathways, such as sulfate reduction (e.g., Visscher et al., 1998; Paerl et al., 2001), are also integral in carbonate cementation and localized alkalinity generation. Indeed, sequence analysis of small subunit rRNA genes amplified with PCR from genomic DNA showed that anoxygenic phototrophs represent a considerable fraction of biomass in the modern stromatolite communities of Hamelin Pool, Shark Bay, Australia (Papineau et al., 2005). Recently, Bosak et al. (2007) experimentally demonstrated that the anoxygenic phototroph, *Rhodospseudomonas palustris*, stimulates the precipitation of calcite in saturated solutions and builds stromatolite-like structures.

While 2 α -methylhopanes were first considered diagnostic of oxygenic photosynthesis, they may have a structural function and are not related to cell metabolism. Indeed, several facultative and obligate anaerobes possess the genes for hopanoid biosynthesis, and *Geobacter sulfurreducens* produces a wide variety of complex hopanoids structurally related to 2 α -methylhopane under strictly anoxic conditions in pure culture (Härtner et al., 2005; Fischer and Pearson, 2007). Moreover, it was recently demonstrated that an anoxygenic Fe(II)-oxidizing phototroph, *Rhodospseudomonas palustris*, generates substantial quantities of 2-methylhopanoids in the absence of oxygen (Rashby et al., 2007), which renders their presence in ancient rocks alone as an unsatisfactory marker for a specific metabolism.

Pigment biomarkers may offer further evidence of a microbial role in BIF. Okenane, the fossil hydrocarbon biomarker of the carotenoid pigment precursor, okenone, was recently found in the 1.64 billion-year-old Barney Creek Formation in northern Australia, a marine, sub-wavebase base succession. This pigment is exclusively found in purple sulfur bacteria and in recent sediments under euxinic conditions (Brocks, 2005).

Isotopic evidence and the BIF depositional mechanism

The Fe isotope composition of iron minerals in BIFs is markedly different from the homogenous values seen in

igneous rocks and many modern marine sediments ($\delta^{56}\text{Fe}$ $0.00 \pm 0.05\text{‰}$). Specifically, the hematite, magnetite, Fe-carbonate, and pyrite Fe isotope compositions reflect the various processes contributing to BIF formation; equilibrium fractionation of minerals, a variation in the fluid isotope composition from which the minerals precipitated, as well as microbial processes (Johnson et al., 2003; Johnson and Beard, 2005).

In an effort to elucidate the role of microorganisms in the formation of BIF, the Fe isotope fractionation carried out by Fe metabolizing microorganisms was analyzed in controlled laboratory studies of both pure and enrichment cultures. These show that ferric hydroxides are enriched in the heavy isotope relative to Fe(II) for anoxygenic Fe(II)-oxidizing phototrophy ($1.5 \pm 0.2\text{‰}$) (Croal et al., 2004), microbially catalyzed aerobic Fe(II) oxidation at low pH (Balci et al., 2006), aerobic chemical oxidation (Bullen et al., 2001), and UV Fe(II) oxidation (Straton et al., 2006), suggesting that all major processes produce similar Fe isotope fractionations.

The isotopic fractionations reported from laboratory experiments correlate well in part with the values recovered from Archean to early Proterozoic banded rocks of the Transvaal Supergroup, South Africa. $^{56}\text{Fe}/^{54}\text{Fe}$ values in hematite are as high as $+0.75$ to $+1.0\text{‰}$ (Johnson et al., 2003) when compared to the Fe from hydrothermal vents ($\pm 0\text{‰}$). As UV photooxidation was recently ruled out as a significant BIF deposition mechanism (Konhauser et al., 2007), these positive to near-zero $\delta^{56}\text{Fe}$ values are even consistent with (although not proof of) phototrophic Fe(II) oxidation in the early Archean oceans. However, the similarity in values from anoxygenic phototrophs with those of Fe(III) oxides formed by chemical oxidation and microbially catalyzed aerobic Fe(II) oxidation make it difficult to distinguish the key biotic and abiotic processes (Bullen et al., 2001; Balci et al., 2006). Iron isotope fractionation during oxidation itself is obviously independent of the oxidation mechanism (chemical or biological) because of the very rapid isotopic exchange between aqueous Fe^{2+} and Fe^{3+} , allowing isotopic equilibrium to be attained between reduced and oxidized aqueous species. Moreover, in these ancient formations interpretation of the isotopic signature is complicated by the complexity of the depositional environments, the diagenetic processes which have altered the Fe mineralogy, including the infiltration of external fluids during diagenesis and/or low temperature metamorphism which may have erased the primary isotope record (Hoefs, 1997; Johnson et al., 2003). Indeed, the large variation of $\delta^{56}\text{Fe}$ (-2.5 to $+1.0\text{‰}$ relative to the bulk Earth) in late Archean and early Paleoproterozoic BIFs from the Transvaal Supergroup, South Africa incorporates the entire range of values measured on the Earth.

The carbon isotopic record of BIFs is constrained by the low occurrence of organic carbon (0.5% [w/w], Beukes and Klein, 1992) in these structures. Carbon isotope signatures observed in contemporaneous formations may offer information about organisms which were present at the

time of deposition, but whose record was erased, for example, by postdeposition diagenetic processes. In such ancient formations, negative carbon isotope signatures are often interpreted as an indicator of life. Organisms transform inorganic carbon (e.g., CO_2 or HCO_3^-) via autotrophic pathways into organic carbon, preferentially incorporating the lighter isotope, ^{12}C , into the organic phase and producing residual CO_2 enriched in the heavier isotope, ^{13}C . Cyanobacteria, for example, display a $\delta^{13}\text{C}$ range of -4 to -35‰ (Schidlowski, 2000). For example, early photosynthesis has been linked to mat-forming communities in microfossiliferous units within Archean formations from Western Australia and South Africa (e.g., Altermann and Kazmierczak, 2003; Tice and Lowe, 2004) by carbon isotopic values ranging from -20‰ to -35‰ , as well as the $-31.0\text{‰} \pm 4.7$ values from organic carbon in early Proterozoic cherts (Strauss et al., 1992).

Key to this approach is the consideration of overlapping degrees of fractionation produced by various carbon fixation pathways (reductive acetyl-CoA, reductive citric acid, Calvin cycle, and hydroxypropionate). This makes it impossible to determine whether these putative biological residues were remnants of chemolithoautotrophs, evidence for early photosynthesis, or abiological C-isotopic fractionations, such as those associated with Fischer-Tropsch type processes ($\Delta^{13}\text{C}$ between -50‰ and -100‰).

Theories of iron and silica mineral layering

One of the characteristic features of BIF are the alternating Fe-rich (hematite, magnetite, and siderite) and the silicate/carbonate (chert, jasper, dolomite, and ankerite) layers that form bands varying in thickness from the microscale (μm in thickness) to meter-thick units (Trendall, 1968; Klein and Beukes, 1992; Klein, 2005). Some deposits, such as in the Dales Gorge Member, Hamersley Group, Western Australia, show laterally contiguous layers up to a 100 km in distance. This suggests that some unifying trigger of iron and silicate mineral precipitation exists over large areas with some regularity, most likely one which largely subdues the precipitation of one mineral while stimulating that of the other. Furthermore, given the range of band thickness from the micro- to macro-scale, as well as the complex mineralogy, it is most likely that layering in BIF is determined by a multilayered mechanism; one producing primary layering and a second mechanism acting post deposition via diagenesis.

Following this observation, many models attribute the primary genesis of micro and mesobands to seasonal stratification, or to yearly or decadal climatic cycles. Episodic hydrothermal pulsation and upwelling of Fe(II)-rich waters into depositional basins already saturated with dissolved silica have been invoked to explain these bands; silicification is driven by seasonal evaporation of basin waters (Holland, 1973; Garrels, 1987; Jacobsen and Pimentel-Klose, 1988; Siever, 1992). This mechanism, however, does not explain the laterally contiguous fine-scale banding, nor does it resolve why the iron and silica

do not co-precipitate but rather form distinct mesobands (Trendall, 1968; Garrels, 1987; Morris, 1993). Furthermore, in light of increasing evidence for an active microbial component in the Fe cycle (Johnson et al., 2003), the potential importance of microorganisms in BIF deposition models has been suggested. Indeed, a mechanism of alternating Fe and silicate mineral layer deposition with a microbial driver triggered by temperature has been recently presented (Posth et al., 2008).

Diagenesis in BIFs: oxidation and the reduction of Fe(III) minerals

The average oxidation state of $\text{Fe}^{2.4+}$ can be described by the simultaneous deposition of Fe(II) and Fe(III). Yet, this mixed oxidation state can also be explained by partial biotic or abiotic diagenetic re-reduction of precipitated Fe(III) to Fe(II). Experimental studies testing such diagenetic mineral transformations in the presence and in the absence of biomass have not yet been reported. Nonetheless, the presence of magnetite as (1) disseminated grains within but obscuring sedimentary laminae, (2) laminated beds that clearly truncate sedimentary layering, (3) layer-discordant veins, and (4) cleavage fills, suggests such a secondary origin (Ewers and Morris, 1981; Krapež et al., 2003).

The diagenetic or microbial modification of Fe(III) after sedimentation to produce siderite (FeCO_3) and magnetite (Fe_3O_4) requires a reductant. Even if a surface water oxic zone was generated by cyanobacterial activity (Summons et al., 1999), deep waters remained anoxic (e.g., Canfield, 1998). The dominant anaerobic respiratory processes would have oxidized fermentation products in the bottom waters and/or shallow sediments (Rothman et al., 2003). The scarcity of O_2 limited both nitrate and sulfate. This is supported by both negligible sulfur isotopic fractionations between late Archean and early Paleoproterozoic sulfide and sulfate minerals (Strauss, 2003), as well as the absence of pyrite in BIF, except in association with interlayered shaley units (Ewers and Morris, 1981). The significance of manganese pathways is also refuted by the low relative concentrations of Mn(II) released in hydrothermal effluent, as well as the lack of phototrophic or nitrate-independent Mn(II) oxidizing bacteria in modern environments. In contrast, abundant ferric hydroxide deposited as BIF may point to the importance of a microbial process which coupled the oxidation of organic carbon, dead planktonic bacteria, to the reduction of ferric iron producing such reduced iron mineral phases.

Evidence of BIF diagenesis via ancient microbial Fe(III) reduction comes from Fe isotopic ratios in Fe-bearing minerals from Archean sedimentary rocks that closely mimic those observed during modern dissimilatory Fe(III) reduction. For instance, analyses of carbon- and magnetite-rich rocks, from the 2.9 Gyr Rietkuil Formation, Witwatersrand Supergroup, South Africa, revealed $\delta^{56}\text{Fe}$ values as low as -2.3‰ (Yamaguchi et al., 2005). These negative fractionations are very similar to what might be expected from multiple stages of Fe(III)

reduction (Johnson et al., 2004), where each single-step bacterial Fe(III) reduction leads to isotopically light ($\delta^{56}\text{Fe} < 1.2\text{‰}$) aqueous Fe(II) relative to the initial ferric hydroxide substrate (Icopini et al., 2004). The importance of Fe(III) reduction as a means to explain the iron fractionations has, however, been challenged by Rouxel et al. (2005). They suggested that highly variable, but negative values in pyrite from black shales (0.5‰ to -3.5‰) between 2.8 and 2.3 Ga more likely reflect the initial deposition of Fe oxides (e.g., BIFs) which preferentially removed isotopically heavy ^{56}Fe , driving the ocean waters to the negative $\delta^{56}\text{Fe}$ values recorded in pyrite. This interpretation is consistent with the notion that partial biological and abiological processes oxidized the dissolved Fe(II) brought into the shallow waters, but is problematic in light of recent studies showing significant isotopic variations for minerals within close proximity and thus, time of deposition (Johnson et al., 2008). This variation is perhaps most easily explained if the Fe isotopes reflect diagenetic pathways and not the bulk seawater (Johnson et al., 2008).

BIF diagenesis and the Archean marine Fe cycle

BIFs have recently been studied to develop a model of the Archean marine Fe cycle. In doing so, Konhauser et al. (2005) made two assumptions. First, they assumed that the bulk of the Fe(II) component in Fe-rich BIF-type macrobands formed diagenetically through biological Fe(III) reduction, i.e., the magnetite is not primary. Based on a predicted rate of Fe(III) deposition annually (1 mm year^{-1}), they then quantified the electrons that were needed to generate the amount of magnetite as reported in BIF (one third of Fe minerals; Morris, 1993). Second, they quantified the amount of photosynthetic Fe(II)-oxidizer biomass that may have been generated in the photic zone of the water column (based on Kappler et al., 2005), in order to estimate the amount of Fe recycled prior to burial. The results demonstrated that under ideal growth conditions, as much as 70% of the biologically formed Fe(III) could have been recycled back into the water column via fermentation and organic carbon oxidation coupled to microbial Fe(III) reduction. It was also suggested that some of the biomass may have been ultimately consumed via methanogenesis, i.e., coupling the oxidation of acetate or H_2 to methane formation. The hypothesis is to some extent corroborated with the analyses of kerogens (extracted from rocks 2.8 and 2.6 Gyr) with highly negative $\delta^{13}\text{C}$ signatures (between -40‰ and -60‰) that possibly formed as the result of methanogenic ^{12}C -rich gas production, the incorporation of the methane into the biomass of methanotrophic bacteria and inevitably the preservation of ^{12}C -enriched organic matter (Hayes, 1983).

Summary

Banded iron formations (BIFs) have been studied for decades in regard to their importance as an economically

viable source of iron ore, but their significance also extends to their potential as archives of the early Earth environment.

In spite of this effort, the mechanism of their deposition and in particular whether microorganisms drove the precipitation of BIF minerals, is still uncertain. Increasing evidence of a predominantly anoxic Earth until ~2.5–2.4 Ga forces the investigation of O₂-independent mechanisms for BIF deposition. For this reason, recent studies have explored the long-standing proposition that Archean BIFs may have been formed, and diagenetically modified, by anaerobic microbial metabolisms.

BASALT (GLASS, ENDOLITHS)

Ingunn H. Thorseth
 University of Bergen, Bergen, Norway

Synonyms

Endolithic microorganisms in basaltic glass; Microbial life in glassy basalt

Definition

Basalt endoliths. Microorganisms that colonize and live inside fractures, vesicles, and other cavities in basaltic rocks.

Basalt. The most common volcanic rock formed by eruptions of magma of basaltic composition.

Seafloor basalt. Basalt that is exposed at the seafloor, most commonly in or close to the ocean spreading ridge axes where the crust is young, or at intraplate seamounts.

Subseafloor basalt. Basalt that has been buried by younger lava flows and/or deep-sea sediments, as the crust aged and moved away from the spreading ridges.

Basaltic glass and endolithic microorganisms

Introduction

Basalt is continuously formed during volcanic eruptions along the global mid-ocean ridge system, and constitutes the upper 0.5–1 km thick layer of the ocean crust which covers more than 50% of the Earth's surface. When the basaltic magma is extruded into the cold seawater, the 1–2 cm thick outermost surface layer is cooled so rapidly that its chemical species do not have enough time to be arranged into minerals, but freeze to an amorphous glass rind. These glassy margins become heavily fractured due to cooling-related contraction, and the fracture networks provide an immense surface area for rock-water interactions and colonization by microorganisms. As the basaltic glass dissolves and alters more quickly than the minerals (pyroxene, plagioclase) in the crystalline interior of the lava, the glassy proportion plays an important role in the alteration of the ocean crust and the chemical exchange with the ocean water. The alteration is not only controlled by physiochemical factors but also by microbial processes, implied by the presence of endolithic microorganisms (see *Endoliths*) within the glassy margins. The microbial

activity may, on the other hand, be controlled by the geological environment, which includes a variety of complex fluid temperature and chemistry conditions ranging from seafloor weathering to various hydrothermal systems.

Basaltic glass alteration

Low-temperature alteration of basaltic glass results in the formation of concentrically zoned rims of a yellow-brown, hydrous residual alteration product, frequently called palagonite, along the outer surfaces, and internal vesicles and fractures of the glassy margins of lava flows. The altered glass is amorphous (gel-palagonite) to poorly crystalline with clayish character (fibropalagonite) (e.g., Stroncik and Schmincke, 2001), and is usually highly enriched in oxidized Fe and Ti, and depleted in Si and alkaline and alkaline earth elements compared to the fresh, parental glass. The term palagonite was used for the first time by von Waltershausen in 1845 for the brown groundmass of a tuff from Palagonia, Sicily, and was then thought to be a new mineral phase. Although palagonite was later shown to be a heterogeneous material, the term has commonly been used in the literature. However, several authors now recommend referring to this material as altered glass. During the last 2 decades, various field and laboratory studies have shown that the alteration rate and the chemical and crystalline characteristics of the altered glass strongly depend on the physiochemical and hydrological conditions (e.g., Crovisier et al., 2003). The understanding of how the endolithic microorganisms in the glassy margins of basaltic lava flows influence and interact with the alteration process is, however, still poor.

Evidence of microbial life in glassy basalt

The first in situ observations of endolithic microorganisms in basaltic glass was reported from a scanning electron microscopy (SEM) study of recent (<1 million years old (Ma)) volcanic glass deposits from Iceland (Thorseth et al., 1992). Microbial biofilms together with irregular alteration fronts at the fresh-altered glass boundary lead to the suggestion that the degradation of the volcanic glass could be biocatalyzed by the development of more aggressive microenvironments in the near vicinity of the microbial cells. This was subsequently supported by experimental alteration studies, where development of corrosion marks in the glass surface only was observed in combination with biofilm formation and not in sterile controls (Thorseth et al., 1995a; Staudigel et al., 1995, 1998). Similar alteration textures resembling microbial cell morphologies observed in glassy margins of 6 Ma ocean basalt, sampled 432 m below the seafloor at the Costa Rica Rift during the Ocean Drilling Program (ODP) Leg 148, were then stained using DNA-specific dyes to confirm the presence of DNA within these structures (Thorseth et al., 1995b; Giovannoni et al., 1996; Furnes et al., 1996). Further fluorescence in situ

is then reduced to glyceraldehyde-3-phosphate which can be used to form glucose or other organic compounds. However, only one of six glyceraldehyde-3-phosphate molecules leaves the Calvin cycle while the rest is used for the regeneration of the carbon dioxide acceptor ribulose-1,5-bisphosphate which requires more ATP (Figure 1b; for more details on Calvin cycle, see, e.g., Lawlor, 2001; Heldt, 2003).

Anoxygenic photosynthesis

Anoxygenic photosynthesis, which can be found in purple bacteria, green sulfur bacteria, green non-sulfur bacteria, and heliobacteria, differs from oxygenic photosynthesis in that it requires only one photosystem and, since no splitting of water occurs, no oxygen is produced. The photosystem used by purple bacteria and green nonsulfur bacteria is similar to the PSII of plants and cyanobacteria, but contains bacteriochlorophyll instead of chlorophyll. The electron transport is cyclic since the electrons return to the reaction center after passing through a series of electron carriers. The product of the electron transport in the photosystem is ATP. Purple bacteria and green nonsulfur bacteria must oxidize inorganic or organic compounds such as H_2S , H_2 , succinate, or malate to provide the reduction potential necessary for carbon fixation. By using these compounds as electron donors, NAD^+ (nicotinamide adenine dinucleotide) is reduced to $\text{NADH} + \text{H}^+$ in a process called reverse electron transport. Purple bacteria use the Calvin cycle to fix carbon dioxide while green non-sulfur bacteria use a special process called 3-hydroxypropionate pathway.

Green sulfur bacteria and heliobacteria contain a photosystem that resembles the PSI of oxygenic photosynthetic organisms. It has a cyclic electron flow, but here NAD^+ can be reduced directly. Green sulfur bacteria use the reverse Krebs cycle to fix carbon dioxide, while heliobacteria are photoorganotrophs (for more details on anoxygenic photosynthesis, see, e.g., Whitmarsh and Govindjee, 1999; Madigan et al., 2009).

Summary

The light reactions of photosynthesis use the energy of sunlight to provide chemical energy and reducing power in the form of ATP and $\text{NADPH} + \text{H}^+$, respectively, which can then be used in the light-independent reactions to fix carbon dioxide and to convert it into carbohydrates. During the oxygenic photosynthesis of plants and cyanobacteria, water is split and dioxygen is released, whereas anoxygenic photosynthetic organisms such as purple bacteria, green sulfur bacteria, green nonsulfur bacteria, and heliobacteria do not produce oxygen.

Barophilic bacteria

Definition and introduction

Modern deep-sea microbiology was born in the twentieth century, thanks mainly to the efforts of Claude E. ZoBell, Frank H. Johnson, Richard Y. Morita, Holger W. Jannasch, A. Aristides Yayanos, Koki Horikoshi, and others. ZoBell and coworkers were the first group to study the effect of hydrostatic pressure on microbial activity in the deep sea (ZoBell and Johnson, 1949). They coined the term “barophile” to describe bacteria that have “a requirement for increased pressure for growth, or by increased growth at pressures higher than atmospheric pressure” (Jannasch and Taylor, 1984). Pelagic sediments taken from the Philippine Trench at more than 10,000 m (>100 MPa) contained 10^4 to 10^5 cells of viable bacteria g^{-1} wet weight of various physiological types (ZoBell and Morita, 1956) including nitrate reducers, sulfate reducers, and ammonifiers. Most of these organisms were obligate barophiles, unable to grow at atmospheric pressure (0.1 MPa).

Yayanos and his group were the first to successfully isolate a pressure-adapted bacterium (strain CNPT3) from amphipods collected from the deep sea at 5,700 m in the Pacific (Dietz and Yayanos, 1978). Strain MT41 was probably the first recognized obligate barophile isolated from a decomposing amphipod, *Hirondella gigas*, from a depth of 10,476 m of the Mariana Trench (Yayanos

et al., 1981). Subsequently, numerous deep-sea barophilic bacterial strains have been isolated from the water column, sediments, intestinal tracts, and decaying parts of invertebrates in the deep sea, many of which have been characterized physiologically and phylogenetically (e.g., DeLong et al., 1997).

In 1995, Yayanos (Yayanos, 1995) suggested a change in nomenclature of pressure-loving bacteria, from baro- (Greek word, weight-loving) philes to piezo- (Greek word, pressure-loving) philes. Piezophilic bacteria are now defined as those prokaryotes that display optimal growth at pressures greater than 0.1 MPa or that showing a requirement for increased pressure for growth (Yayanos, 1995). Based on their response to pressure, piezophiles can be classified as piezotolerant (growth from 0.1 to 10 MPa), piezophilic (10–50 MPa), and hyperpiezophilic bacteria (>50 MPa) (Fang and Bazylnski, 2008). This classification is based on the optimal growth pressure, not the maximum growth pressure, of a piezophilic bacterium. Note that the relative growth rate of these organisms decreases with pressure. The upper limits of life with respect to pressure are not yet defined. For example, *Colwellia* strain MT41 grows at pressures greater than 130 MPa, which is more than hydrostatic pressure at any ocean depth (Yayanos, 1986).

Taxonomy and diversity of deep-sea piezophilic bacteria

Most known cultured piezophilic bacteria belong to one of the following five genera of the γ -subdivision of the Proteobacteria: *Shewanella*, *Photobacterium*, *Colwellia*, *Moritella*, and a genus containing strain CNPT3, recently identified as *Psychromonas* (Nogi et al., 2002). *Shewanella* includes *S. benthica* and *S. violacea*. *Shewanella* species are particularly widely distributed in the deep sea with a broad range of optimal growth pressure conditions from piezophilic to hyperpiezophilic. Representative species include *S. violacea* strain DSS12; *S. benthica* strain PT99; and strains DB1172F, DB1172R, DB21MT-2, DB5501, DB6101, DB6705, DB6906, WHB46, F1A, PT48. *Moritella* includes *M. japonica*, *M. yayanosii*, *M. profunda*, and *M. abyssi*. *Colwellia* includes *C. hadaliensis* and *C. piezophila* with two hyperpiezophilic strains MT41 and BNL-1. *Photobacterium* includes *P. profundum*. *P. profundum* strain SS9 is one of the most extensively studied piezophilic bacteria whose genomic sequence has been reported recently (Vezzi et al., 2005). *Psychromonas* includes *P. kaikoi* and *P. profunda*. Overall, it seems that there is a limited diversity of the cultured piezophilic bacteria which may be an artifact of the use of rich, heterotrophic growth media. It is likely that diversity of piezophilic bacteria will increase as the use of different types of growth media increases (DeLong et al., 1997). For a more detailed taxonomic description of piezophilic bacteria, see Fang and Kato (2010) and Fang and Bazylnski (2008).

Piezophily, piezophysiology and metabolism of piezophilic bacteria

Temperature (T) and pressure (P) are two interrelated environmental parameters that determine piezophilic bacterial growth over a (P, T)-domain. A bacterial isolate is piezophilic if it has a greater generation time at some high pressure than it does at atmospheric pressure when tested at its habitat temperature (Yayanos, 1998). Generally, deep-sea bacteria show strongest piezophilic response to pressure at their upper temperature for growth (typically 15°C) (Kato et al., 1995). Piezophilic strains become more piezophilic at higher temperatures (Kato et al., 1995). The degree of piezophily increases with increasing collection depth or pressure (Yayanos, 1986). Therefore, each piezophilic isolate would have a single maximum growth rate, $k_{\max}$ ($k = \ln 2/\text{doubling time in h}$) at ($P_{k\max}, T_{k\max}$) on a PTk -diagram (Yayanos, 1986).

Deep-sea piezophilic bacteria are stenothermal (Yayanos, 1998) but “eury-piezotic” (being able to tolerate wide range of pressures). The temperature range ($T_{\max} - T_{\min}$) is roughly 10–20°C (Yayanos, 1986), whereas the pressure range is about 40 MPa for bacteria captured at a depth of less than 3,600 m (Jannasch and Taylor, 1984) and 80 MPa for isolates of depths greater than 5,000 m (e.g., Yayanos and DeLong, 1987).

Laboratory and field studies based on substrate utilization have confirmed piezophilic bacterial activity in deep-sea sediments. Deming and Colwell (1985) examined microbial activity in box cores and sediment trap samples collected in the Demerara abyssal plain in the South Atlantic Ocean (4,470 and 4,850 m). Samples were incubated with low levels (<10% above natural abundance) of [^{14}C] glutamate at 3°C and in situ and atmospheric pressure. In both sediment and sinking particulate samples examined, enhanced microbial utilization of [^{14}C] glutamate was observed at in situ pressure, suggesting that indigenous piezophilic bacteria, not the piezo-sensitive microbes originated in shallow surface waters, were metabolically active and functionally predominant in the cycle of naturally low levels of organic matter in the abyssal sediments (Deming and Colwell, 1985). Similar results were obtained in a study conducted on sediment from the Porcupine Abyssal Plain of the Atlantic Ocean (Eardly et al., 2001). Thus, it is highly likely that piezophilic bacterial activity may be widespread in deep sea. However, the proportion of the metabolically/functionally dominant piezophilic bacterial population over the total microbial population in deep sea is unknown.

It is generally believed that the effect of pressure on metabolic processes is secondary to that of temperature. However, based on thermodynamic calculations, Fang and Bazylnski (2008) demonstrated that pressure does have a significant effect on microbial-mediated redox reactions (Figure 1); high pressures reduce the energy yield of O_2 reduction, NO_3^- reduction, and sulfate reduction and increase the energy yield of the reduction of Fe_2O_3 . The additive effect of temperature and pressure

has raised the $p\epsilon^{o'}$ values of the first four reactions commonly taking place at more positive redox potentials and lowered the $p\epsilon^{o'}$ values (electron activity at the biological standard state) for other six reactions that take place at more reducing conditions. Thus, redox reactions prevailing at more oxidative condition (O_2 , NO_3^-/NO_2^- reduction, etc.) yield slightly more energy in the deep-sea low temperature–high pressure conditions, whereas those that dominate in more reducing conditions yield relative less energy, compared to surface environments (25°C , 0.1 MPa).

Lipid biosynthesis and carbon isotope fractionation of piezophilic bacteria

The most abundant lipids detected in piezophilic bacteria are *n*-alkyl, acetogenic lipids (i.e., fatty acids); no polyisoprenoids are detected (Fang, unpublished data). Fatty acids biosynthesized by piezophilic bacteria include C_{12-19}

saturated, monounsaturated, terminal methyl-branched, β -hydroxyl, and cyclopropane fatty acids (Fang et al., 2003; Fang and Bazylinski, 2008). Piezophilic bacteria are unique and distinctive in fatty acid composition in that: (1) they synthesize abundant polyunsaturated fatty acids (PUFA), i.e., eicosapentaenoic acid (EPA, $20:5\omega3$ *cis*-5,8,11,14,17) and docosahexaenoic acid (DHA, $22:6\omega3$ *cis*-4,7,10,13,16,19) and (2) the abundance of unsaturated fatty acids is high and can comprise up to 70% or more of the total fatty acids.

It is generally believed that the carbon isotopic composition of cell components and lipid biomarkers can provide information on modes of microbial metabolism and physiology. The carbon isotope signature is especially useful in deep-sea geomicrobiology for two reasons (Fang and Kato, 2007). First, environmental conditions (temperature and pressure) of the deep sea may exert a greater influence on carbon isotope fractionation in the biosynthesis of fatty acids and therefore the carbon isotopic ratios of individual

Piezophilic Bacteria, Figure 1 Sequence of microbially-mediated reduction reactions based on values of electron activity at biological standard state ($p\epsilon^{o'}$) at 25°C and 1 bar (a) and 2°C and 400 bar (b).

compounds (Fang et al., 2006). Second, the deep-sea piezophilic bacteria possess two simultaneously operating biosynthetic pathways of fatty acids which dictate distinctive carbon isotope signature for the long-chain polyunsaturated fatty acids (Metz et al., 2001).

Recently, Fang et al. (2006) examined carbon isotope fractionation during fatty acid biosynthesis in *Moritella japonica* strain DSK1 and demonstrated that carbon isotope fractionation in biosynthesis of fatty acids of piezophilic bacteria is pressure-dependent. Fatty acids became progressively more depleted in ^{13}C with growth pressure. There was a strong linear correlation between carbon isotopic fractionation and hydrostatic pressure. Overall, piezophilic bacteria fractionate carbon isotopes significantly (14–18‰) more than surface heterotrophic bacteria. Thus, the recycling and re-synthesis of fatty acids by piezophilic bacteria utilizing organic matter originating from primary production will greatly alter the carbon isotope signature of both short-chain bacterial and long-chain planktonic fatty acids in oceanic environments and marine sediments. Further, PUFA had much more negative $\delta^{13}\text{C}$ values than other short-chain saturated and monounsaturated fatty acids. This was attributed to the operation of two different fatty acid biosynthetic systems in piezophilic bacteria: the FAS (fatty acid synthase)- and PKS (polyketide synthases)-based pathways (Fang and Kato, 2007). The FAS-based pathway is one common to surface bacteria which synthesizes typical bacterial fatty acids. The PKS-based pathway is a fundamentally different pathway which involves polyketide synthases (Metz et al., 2001) which catalyze the biosynthesis of long-chain polyunsaturated fatty acids. The PKS pathway appear to be widely distributed in marine bacteria (Wallis et al., 2002) as genes with high homology to the *Shewanella* EPA gene cluster (*Shewanella* sp. SCRC-2738) (Yazawa, 1996) have been found in *Photobacterium profundum* strain SS9 which synthesizes EPA (Allen et al., 1999) and in *Moritella marina* strain MP-1 which produces DHA (Tanaka et al., 1999). Thus, fatty acids (particularly EPA and DHA) and carbon isotope signatures become more informative in deep-sea geomicrobiology.

Conclusions

Piezophilic bacteria are prokaryotes that display optimal growth at pressures greater than 0.1 MPa or that showing a requirement for increased pressure for growth. The deep-sea piezosphere, influenced by hydrostatic pressure, probably represents the largest biotope of the Earth. The evidence obtained thus far suggests that microbial life in the deep sea is diverse and that microbial biomass there can be significant. All of the piezophilic isolates reported thus far are facultatively anaerobic, some demonstrating anaerobic respiration as well as fermentation. It has been shown that the degradation of organic matter by fermentation and anaerobic respiration is the principal energy generation processes in both surface and subsurface marine sediments (Parkes et al., 2005). Thus, marine bacteria

must play an important role in the overall ocean carbon cycle. These microorganisms surely influence the surface of the Earth by changing the chemistry of the ocean and by affecting the rate of organic carbon burial, with consequences for both the marine carbon cycle and global climate (Fang and Bazylinski, 2008).

PORE WATERS

Sabine Kasten
 Alfred Wegener Institute for Polar and Marine Research,
 Bremerhaven, Germany

Synonyms

Interstitial waters

Definition

The term *pore water* refers to the water contained in the interstices/pore space of aquatic sediments.

Introduction

Extracting pore waters and analyzing various dissolved constituents is a central approach in marine sediment

geochemistry, biogeochemistry, and geo(micro)biology. The ensuing pore-water concentration-depth profiles are used (a) to characterize the geochemical environment and redox zonation of aquatic sediments (Froelich et al., 1979; Berner, 1981; Postma and Jakobsen, 1996), (b) to infer and identify early diagenetic and biogeochemical processes by compounds which are either consumed or released by the particular reaction (Reeburgh, 1969; Froelich et al., 1979), (c) to calculate diffusive fluxes of dissolved constituents (Hensen et al., 2006; Zabel and Hensen, 2006), and (d) to model reaction and turnover rates of biogeochemical and diagenetic processes – including mineral dissolution and precipitation (Berner, 1980; Van Cappellen and Wang, 1995; Boudreau, 1996). Furthermore, pore-water profiles are applied to quantify the abundance of gas hydrates in marine deposits (Ussler and Paull, 2001; Bohrmann and Torres, 2006) and to study subsurface fluid flow (Saffer and Scretton, 2003).

Pore-water profiles evolve as a consequence of the complex interplay between successive microbial degradation of organic matter by various electron acceptors and a broad spectrum of secondary diagenetic reactions on the one hand and different transport processes (diffusion, advection, bioturbation, and bioirrigation) on the other hand. Due to the close coupling between geochemistry and microbiology, concentration-depth profiles of dissolved chemical species often point to “new” – i.e., to date unknown – biogeochemical processes and metabolic pathways and pave the way for the discovery of novel microorganisms or consortia of microbes which mediate the particular reactions. A well-known example is the process of anaerobic oxidation of methane by sulfate (AOM) which was already postulated to occur on the base of pore-water profiles in the late 1960s (Reeburgh, 1969). Only about 30 years later, new and advanced techniques in molecular biology ultimately were able to prove the existence of microbial consortia of archaea and sulfate-reducing bacteria mediating this process (Boetius et al., 2000; Orphan et al., 2001).

Extraction and analyses of pore waters

The classical ways of extracting pore waters are (a) by squeezers where pressure is applied either by an inert gas (e.g., nitrogen, argon) or with a hydraulic press, or (b) by centrifuging and subsequent decanting (Gieskes et al., 1991; Schlüter, 1990; De Lange et al., 1992; for a review see Schulz, 2006, and references therein). In recent years, a new technique for a rapid and more or less nondestructive collection of pore waters from marine sediments has been developed and established – the so-called rhizon sampling (Seeberg-Elverfeldt et al., 2005; Dickens et al., 2007). Rhizon samplers are thin tubes of hydrophilic porous polymer which have a minimum pore size of 0.1 µm. They are inserted into the sediment and are connected to either vacuum vials, spring-loaded syringes, or operated with peristaltic pumps which allow to

BASALT (GLASS, ENDOLITHS)

Ingunn H. Thorseth
 University of Bergen, Bergen, Norway

Synonyms

Endolithic microorganisms in basaltic glass; Microbial life in glassy basalt

Definition

Basalt endoliths. Microorganisms that colonize and live inside fractures, vesicles, and other cavities in basaltic rocks.

Basalt. The most common volcanic rock formed by eruptions of magma of basaltic composition.

Seafloor basalt. Basalt that is exposed at the seafloor, most commonly in or close to the ocean spreading ridge axes where the crust is young, or at intraplate seamounts.

Subseafloor basalt. Basalt that has been buried by younger lava flows and/or deep-sea sediments, as the crust aged and moved away from the spreading ridges.

Basaltic glass and endolithic microorganisms

Introduction

Basalt is continuously formed during volcanic eruptions along the global mid-ocean ridge system, and constitutes the upper 0.5–1 km thick layer of the ocean crust which covers more than 50% of the Earth's surface. When the basaltic magma is extruded into the cold seawater, the 1–2 cm thick outermost surface layer is cooled so rapidly that its chemical species do not have enough time to be arranged into minerals, but freeze to an amorphous glass rind. These glassy margins become heavily fractured due to cooling-related contraction, and the fracture networks provide an immense surface area for rock-water interactions and colonization by microorganisms. As the basaltic glass dissolves and alters more quickly than the minerals (pyroxene, plagioclase) in the crystalline interior of the lava, the glassy proportion plays an important role in the alteration of the ocean crust and the chemical exchange with the ocean water. The alteration is not only controlled by physiochemical factors but also by microbial processes, implied by the presence of endolithic microorganisms (see *Endoliths*) within the glassy margins. The microbial

activity may, on the other hand, be controlled by the geological environment, which includes a variety of complex fluid temperature and chemistry conditions ranging from seafloor weathering to various hydrothermal systems.

Basaltic glass alteration

Low-temperature alteration of basaltic glass results in the formation of concentrically zoned rims of a yellow-brown, hydrous residual alteration product, frequently called palagonite, along the outer surfaces, and internal vesicles and fractures of the glassy margins of lava flows. The altered glass is amorphous (gel-palagonite) to poorly crystalline with clayish character (fibro-palagonite) (e.g., Stroncik and Schmincke, 2001), and is usually highly enriched in oxidized Fe and Ti, and depleted in Si and alkaline and alkaline earth elements compared to the fresh, parental glass. The term palagonite was used for the first time by von Waltershausen in 1845 for the brown groundmass of a tuff from Palagonia, Sicily, and was then thought to be a new mineral phase. Although palagonite was later shown to be a heterogeneous material, the term has commonly been used in the literature. However, several authors now recommend referring to this material as altered glass. During the last 2 decades, various field and laboratory studies have shown that the alteration rate and the chemical and crystalline characteristics of the altered glass strongly depend on the physiochemical and hydrological conditions (e.g., Crovisier et al., 2003). The understanding of how the endolithic microorganisms in the glassy margins of basaltic lava flows influence and interact with the alteration process is, however, still poor.

Evidence of microbial life in glassy basalt

The first in situ observations of endolithic microorganisms in basaltic glass was reported from a scanning electron microscopy (SEM) study of recent (<1 million years old (Ma)) volcanic glass deposits from Iceland (Thorseth et al., 1992). Microbial biofilms together with irregular alteration fronts at the fresh-altered glass boundary lead to the suggestion that the degradation of the volcanic glass could be biocatalyzed by the development of more aggressive microenvironments in the near vicinity of the microbial cells. This was subsequently supported by experimental alteration studies, where development of corrosion marks in the glass surface only was observed in combination with biofilm formation and not in sterile controls (Thorseth et al., 1995a; Staudigel et al., 1995, 1998). Similar alteration textures resembling microbial cell morphologies observed in glassy margins of 6 Ma ocean basalt, sampled 432 m below the seafloor at the Costa Rica Rift during the Ocean Drilling Program (ODP) Leg 148, were then stained using DNA-specific dyes to confirm the presence of DNA within these structures (Thorseth et al., 1995b; Giovannoni et al., 1996; Furnes et al., 1996). Further fluorescence in situ

hybridization (FISH) were used to document the existence of indigenous Bacteria (see *Bacteria*) and Archaea (see *Archaea*) in this glassy basalt (Torsvik et al., 1998). Additional evidence for microbial activity in oceanic basalt came from the demonstration of carbon and nitrogen enrichments in the alteration textures (Giovannoni et al., 1996; Torsvik et al., 1998), and stable carbon isotope fractionation from disseminated carbonate that is consistent with microbial processes (Torsvik et al., 1998). During the last decade, further morphological, geochemical, biomolecular, and cultivation studies of seafloor and subseafloor basalts of various ages, water depths, depth of burial and temperature regimes, as well as of hydrothermal fluids, have revealed that diverse endolithic microbial communities colonize the upper oceanic crust at the spreading ridges. In addition, detection of comparable alteration textures and geochemical and isotopic biosignatures (see *Biosignatures in Rocks*) in lava margins of ancient oceanic basalt implies that microbial life and associated biodegradation in the ocean crust occurred very early in the Earth's history (Furnes et al., 2004; Staudigel et al., 2006).

Microbial life in seafloor basalt

Several electron microscopy studies of seafloor lavas from the Arctic Mohs and Knipovich Ridges and the Australian Antarctic Discordance (AAD) area of the Southeast Indian Ridge (SEIR) have demonstrated that a diverse and numerous endolithic microbial community of various coccoid, rod-shaped, filamentous, and stalked cells colonize the fracture network in the glassy margins of the basalts soon after its formation and exposure to the cold, oxygenated seawater (Figure 1) (Thorseth et al., 2001, 2003; Kruber et al., 2008a, b). The presence of microbial cells in lavas from different regions of the seafloor suggests that microbial colonization and growth is a general feature of mid-ocean ridge basalts. In very young basalts (0 Ma), the microbial cells are observed in the central fractures attached to the outer surface of alteration rims, within porous zones in the rims, and at the alteration front attached to the fresh glass (Figure 1b and c). The cells act as nucleation sites for precipitation and become encrusted and embedded in the secondary alteration products with time. Alteration rims where porous zones containing numerous hollow, apparently fossilized cells (see *Microbial Biomineralization*), alternate with compact zones lacking distinctive cell structures, indicate that the microbial growth in the fractures is discontinuous (Figure 1b). In older (2.5 Ma) seafloor basalts where the alteration rims are much thicker, no evident cell structures have been observed at the alteration fronts (Figure 1d), but occur in porous zones of the rims closer to the central fracture, and within in the fractures attached to secondary zeolite crystals (Figure 1e). The cells within the rims are much lower in carbon than those in the fractures, indicating that they are fossilized or partially decayed. This implies that

the fluid availability decreases through the alteration rims, away from the fractures (Thorseth et al., 2003).

Biomass

The presence of abundant alteration rims with closely packed microbial cell structures indicate high cell numbers in the glassy margins of young seafloor basalt. However, a significant fraction of these structures are fossilized cells that have accumulated through time. Thus, while the number of living cells measured by real-time quantitative PCR and fluorescence microscopy is estimated to be around 10^6 cells/g of glassy seafloor basalt (Einen et al., 2008), calculations based on the organic carbon content in the altered glass indicate a considerable larger endolithic biomass (around 10^9 cells/g of glassy basalt, assuming 10^{-13} g of carbon in one cell and that 1% of the glass is altered (Kruber et al., 2008a)). Even if this calculation is highly tentative, the discrepancy suggests that the biogenic material in the fossilized cells is preserved for some time before it is completely decayed. This is further supported by detection of carbon in individual cell encrustations by microanalytical techniques (Thorseth et al., 2003). Due to the highly porous and fractured character of the upper extrusive basalt layer at spreading axes, it is supposed that a similar biomass may also be present in the subseafloor basalt at depths down to several tens to hundreds of meters.

Phylogenetic and metabolic diversity

The endolithic microbial communities in the Arctic seafloor basalts are shown to be almost exclusively from the domain *Bacteria*, and only small proportions are from the *Archaea* domain (Einen et al., 2008). The most frequently retrieved bacterial DNA sequences from these basalts affiliate with the *Gamma-proteobacteria*, *Alpha-proteobacteria*, *Chloroflexi*, *Firmicutes*, and *Actinobacteria*, while the archaeal sequences were restricted to the marine Group 1 *Crenarchaeota* (Lysnes et al., 2004a). The phylogenetic diversity of basalt endoliths is found to be distinct and different from those observed in the surrounding deep seawater.

In contrast to deep-sea sediments where biogenic debris from the photic zone provides an important energy and carbon source for the inhabiting microbial communities, the basaltic basement is rich in reduced inorganic compounds that together with dissolved inorganic carbon may support growth of lithoautotrophic (see *Chemolithotrophy*) microorganisms (Bach and Edwards, 2003). Mid-ocean ridge basalts typically have iron contents of 7–9 wt%, of which approximately 80% is in the divalent state. As the basaltic glass alters to palagonite, Fe(II) is predominantly oxidized to Fe(III). The alteration of the glass may thus provide both potential energy and electron acceptors for the endolithic microbial communities. Observations of branching, twisted filamentous structures resembling stalks of the neutrophilic, iron-oxidizing bacteria (see *Fe(II)-Oxidizing Prokaryotes*) *Gallionella*

Basalt (Glass, Endoliths), Figure 1 Scanning electron microscopy images of seafloor basalts. (a) Glassy margin of zero-age basalt from the Mohs Ridge with typical network of cracks and fractures where the glass reacts with the seawater and alters to palagonite; (b) close up of fracture with regular alteration rims at both sides, showing alternating solid and porous zones with abundant cell encrustations (hollow spheres); (c) microbial cells attached to the fresh glass at the alteration front in the Arctic seafloor basalt; (d) interface between fresh and altered glass in 2.5 Ma seafloor basalt from the SEIR, where no evident cell structures occur; (e) zeolite crystal in fracture of the 2.5 Ma basaltic glass with clusters of coccoid cells attached to it; (f) filamentous structures resembling stalks of iron-oxidizing bacteria (see *Gallionella*) within fracture of zero-age basaltic glass from the Knipovich Ridge.

ferruginea (see *Gallionella*) and the newly characterized *Mariprofundus ferrooxidans* (Emerson et al., 2007) at the glass-palagonite interface (Figure 1f) indeed indicate that microbial oxidation of Fe(II) from the dissolving glass is associated with the weathering of basalt (Thorseth et al., 2001). Culturing of novel Fe-oxidizing lithoautotrophs from inactive sulfide chimneys (Edwards et al., 2003) furthermore suggests that other, previous unknown Fe-oxidizing species could occur in basalt as well. In addition, preferential accumulation of manganese in some cell encrustations can be explained by the activity of Mn-oxidizing bacteria (Thorseth et al., 2001, 2003; Kruber et al., 2008a, b). Isolation of numbers of diverse heterotrophic Mn(II)-oxidizing bacteria from the surfaces

of recent basalt flows from the Loihi Seamount strongly support this (Templeton et al., 2005). Results from DNA analyses and enrichments have furthermore shown that Fe-reducing bacteria (see *Fe(III)-Reducing Prokaryotes*) affiliating with *Shewanella frigidimarina* (see *Shewanella*) as well as other unknown Fe-reducers also are associated with the weathering of glassy seafloor basalt (Lysnes et al., 2004a). Microbial catalyzed cycling of Fe (and Mn) may thus be important in low-temperature alteration of oceanic basalt. Although seafloor basalts are in direct contact with the ambient, oxygenated seawater, the presence of microaerophilic microorganisms such as *G. ferruginea* and *M. ferrooxidans* demonstrates that redox-gradients are formed in the seawater-filled fractures

during an early stage of alteration and microbial colonization of glassy margins. The detection of Fe-reducers furthermore indicates that anaerobic microenvironments locally develop in the fracture network of the glassy margins. Neither sulfate reducing bacteria (SRB) nor secondary sulfide phases, which are commonly reported from marine sediment, have however, been detected.

Production of methane from hydrogen and carbon dioxide during enrichments indicates in addition that lithotrophic methanogens are present in glassy seafloor basalt, although DNA sequences from basalt and enrichments have not matched DNA sequences from any known methanogens (Lysnes et al., 2004a). The hydrogen source for methanogenesis in the basaltic glass is however, unclear. Degassing from deep magma chambers or production by high-temperature water-rock interactions associated with volcanic eruptions and serpentinization of ultramafic rocks (Holloway and O'Day, 2000; Kelley et al., 2002) are all unlikely processes at the actual sampling sites. Simulations of geochemical reactions between water and ultramafic rocks indicate, however, hydrogen production also at low temperatures (Palandri and Reed, 2004). Hydrogen production during low-temperature alteration of basalt has, however, been a matter of debate (e.g., Andersen et al., 1998). Hydrogen could, on the other hand, be produced by microbial processes.

Microbial impact on the alteration: biomineralization and microbial mediated dissolution

The microbial catalysed oxidation and reduction of iron and manganese, and nucleation and precipitation of alteration products on the microbial cells and their extracellular material, are likely to partially control the mobility of elements from the dissolving glass and reacting seawater. In addition, as the microbial growth and fossilization are main controls on the porosity and texture of the alteration rims, these processes are also expected to affect the fluid exchange rate and thus, the dissolution rate in the fractures. Together with the relatively large endolithic biomass, this suggests that the potential microbial impact on the weathering of seafloor basalt and the chemical exchange with the seawater is significant. Observation of pit marks in the glass beneath the attached microbes

(Figure 2a) furthermore suggests that the dissolution of the glass is to some extent controlled by microbial processes (Thorseth et al., 2001). It is, however, not known if the pitting is actively caused by local enhanced microbial dissolution due to the utilization of energy or nutrients present in the glass, or to the passive accumulations of metabolic waste products and the development of corrosive microenvironments at the interface between the microbial cells and the glass. Results from recent laboratory experiments have shown that organotrophs (Daughney et al., 2004) as well as lithoautotrophs (Edwards et al., 2004) have the potential to increase the dissolution rate and the alteration of basalt at the seafloor.

In addition to putative microbial mediated pitting, pit marks of similar form and size to microbes that are filled by hemispherical alteration structures and not by characteristic hollow cell encrustations (Figure 2b) suggest that abiotic processes may produce comparable dissolution textures to microbial processes. Such abiogenic corrosion marks most frequently occur in narrow fractures, which suggest that they are related to dissolution at low water-rock ratios (Kruber et al., 2008a).

Microbial life in subsurface basalt

Drill cores: textural, geochemical, isotope, and biomolecular biosignatures

The first reported evidence of endolithic microbes in basalt from the Costa Rica Rift subsequently stimulated to additional studies of basaltic glass in subsurface rocks from various locations and ages. Most of the studies report of similar textural, geochemical, isotope, and biomolecular evidences for microbial activity in the glass, as in the first report (Furnes and Staudigel, 1999; Fisk et al., 1998, 2003; Furnes et al., 1999, 2001a, b, 2003; Banerjee and Muehlenbachs, 2003; Thorseth et al., 2003; Benzerara et al., 2007). The phylogenetic and metabolic diversity of subseafloor endolithic microbial communities inhabiting oceanic basalts have, however, only been described in the study by Lysnes et al. (2004b), and with more limited data in the study by Fisk et al. (2003).

While abiotic alteration of isotropic basaltic glass is expected to produce regular zoned alteration rims with

Basalt (Glass, Endoliths), Figure 2 (a) Pit marks in the glass with similar form and size as the attached microbial cells; (b) pit marks in the glass that are filled by solid hemispherical alteration structures and not by hollow microbial encrustations.

smooth interfaces between the fresh and altered glasses, the commonly observed irregular alteration fronts have been interpreted to be a result of enhanced dissolution or corrosion mediated by endolithic microbial cells. The most frequently putative biogenic alteration textures reported are (1) irregular patches or zones of individual or coalesced spheres with diameter around 1 μm (also characterized as a granular texture type), and (2) channels or tubular forms 1 μm to few μm wide and up to more than 100 μm in length (Figure 3). After the first reports of DNA-specific staining of altered glass from the Costa Rica Rift, similar textures in samples from other locations have also been shown to contain nucleic acids by fluorescent dyes (Furnes et al., 2001a; Banerjee and Muehlenbachs, 2003; Fisk et al., 2003), as well as elevated amounts of carbon, nitrogen, and phosphorus.

Using alteration textures as discriminating criteria, the extent and importance of biogenic versus abiotic alteration in the oceanic basement has been estimated. Thus, bioalteration has been observed in glasses from 0 to 170 Ma crust at 0–1.5 km depths of burial of lava flows and deep-sea sediments (Fisk et al., 1998; Furnes and Staudigel, 1999; Furnes et al., 2001b; Staudigel et al., 2006). The degree of this bioalteration is highly variable in the upper 300 m of the crust (20–90%), but tends to decrease with depth. The granular texture is found to dominate at all depths. The tubular texture only represents a small fraction of the total bioalteration, and is more common at deeper levels (Furnes and Staudigel, 1999; Furnes et al., 2001b; Staudigel et al., 2006).

The stable carbon isotope composition ($\delta^{13}\text{C}$) of disseminated carbonate provides additional evidence for endolithic microbial activity in altered oceanic basalts. Most investigated samples show $\delta^{13}\text{C}$ values that are significantly lower than magmatic carbon (5 to 7), indicating microbial utilization and oxidation of organic carbon which leads to ^{12}C -enriched CO_2 and carbonate minerals (Furnes et al., 2001a). Positive $\delta^{13}\text{C}$ values of some samples from the Atlantic Ocean have, on the other hand, been explained by lithoautotrophic utilization of H_2 and CO_2

and production of methane. During this process ^{12}C -enriched methane is lost, and the remaining carbonate is enriched in ^{13}C . This could result from more extensive serpentinization and abiotic formation of H_2 at the slow-spreading Atlantic ridge compared to other faster spreading ridges.

Despite the evidence for ongoing microbial activity in subseafloor basalt, few direct observations of evident microbial cell structures, which are easily observed in seafloor basalt, have been reported. Possible candidates are hollow and solid filamentous structures detected in basalt tuff recovered from the Ontong Java Plateau during the ODP Leg 192 (Banerjee and Muehlenbachs, 2003), and hollow spherical structures in pillow basalt recovered from the AAD area of the SEIR during ODP Leg 187 (Thorseth et al., 2003). However, these structures were all supposed to represent fossilized cells.

Petrographic inspection of samples drilled from 14 to 28 Ma ocean crust in the AAD area during the ODP Leg 187 indicated mostly low-temperature, oxygenated alteration conditions. Comparison of 2.5 Ma seafloor basalt from the same area with the much older subseafloor basalt indicated that a significant proportion of the glass alteration developed prior to burial. However, diffuse and highly irregular fresh-altered glass interfaces were only observed in the subseafloor samples and thus most likely developed after burial. These diffuse alteration fronts are apparently caused by dissolution and alteration of the glass into minute globules (0.05–0.2 μm in diameter), and no evident microbial cell structures could be observed to be associated. Some hollow, Mn-containing spherical structures that were observed within zeolite-filled fractures in one sample could represent fossilized equivalents of Mn-rich encrusted, apparently active microbes, observed in 2.5 Ma seafloor basalt (Figure 1e). However, the presence of few cell-like structures in the subsurface glassy basalt suggests that most of the numerous encrusted and fossilized cells developed during the surface stage are totally destroyed or masked by alteration and mineralization during burial. The fossilized cells within zeolite-filled

Basalt (Glass, Endoliths), Figure 3 (a) Petrographic thin section of basaltic glass from Costa Rica Rift, showing tubular structures at the alteration front of palagonite rim along a fracture; (b) close up of A; (c) DNA-specific DAPI staining (blue color) of the tubular structures, indicating the presence of DNA-containing cells.

fractures in subseafloor basalt, on the other hand, possibly indicate that microbial activity continued in the fractures after burial, for as long as circulation continued.

Pit marks and development of irregular alteration fronts both with and without the presence of microbes, and ambient fractures where smooth alteration interfaces are combined with numerous microorganisms attached to the fresh glass, as observed in seafloor basalt, together with irregular alteration fronts without detectable cells in subseafloor basalt, imply that great care should be taken before using alteration textures as the only criterion for microbial activity. Clearly, much more detailed knowledge is needed to fully understand the mechanisms that control both biotic and abiotic pit mark formation in basaltic glasses.

Drill cores: genetic and metabolic diversity

Drilling of 14–28 Ma ocean crust during ODP Leg 187 was partly aimed at studying the genetic and functional diversity of the subsurface microbial community (Christie et al., 2001; Pedersen et al., 2004; Lysnes et al., 2004b). Despite the sparse detection of only fossilized cells by SEM (Thorseth et al., 2003), the identification of a microbial community in these samples by biomolecular techniques that differ from that of surface seawater used as drilling fluid, document the presence of living cells in this old, sediment buried ocean floor basalts, and demonstrate that water-rock interactions also support a diverse endolithic microbial community in old ocean crust. This microbial community is probably present in fluid transporting fractures developed during tectonical events after burial. The nondetection of microbial DNA in a significant proportion of subseafloor samples could thus reflect not only a lower biomass in subseafloor basalts, but also a low number of open fractures in the samples analyzed, compared to seafloor lavas where DNA was retrieved from nearly all investigated samples (Lysnes et al., 2004a, b).

A major fraction of the endolithic microbial community in the subseafloor basalt from the ADD area was shown to be from the domain *Bacteria*, similar to the Arctic seafloor basalt. The five phylogenetic classes *Gamma-proteobacteria*, *Actinobacteria*, *Bacteroidetes*, *Chloroflexi*, and *Firmicutes* that were present in the seafloor basalt were also present in the old subseafloor basalt. The main differences observed were the higher frequency of *Gamma-proteobacteria* in subseafloor basalt, the restricted presence of *Alpha-proteobacteria* in seafloor basalt, and *Beta-proteobacteria* in subseafloor basalt. Fewer and more unequal distributions of the phylotypes in subseafloor samples suggest a decrease in biodiversity and biomass with burial and aging of the crust. The results from this study furthermore indicate that microbial communities inhabiting nonhydrothermal subseafloor basalts participate in the cycling of iron and in the production of methane from H_2 and CO_2 . A major part of the microbial populations showed no close relation to previously characterized microorganisms. The correspondence between

the microbial populations in nonhydrothermal seafloor (Lysnes et al., 2004a) and subseafloor basalts (Lysnes et al., 2004b) may reflect the low-temperature and oxidised conditions, as indicated by the secondary alteration phases and their chemical composition, in both environments. The genetic and physiological diversity of microorganisms in the nonhydrothermal oceanic basalt from the AAD area differ from those reported from hydrothermal fluids from hydrothermal active regions of the ocean crust.

Recently, evidence of the presence of also eukaryotic, fungal life in oceanic basalt was reported (Schumann et al., 2004). The filamentous structures, suggested to represent fossil fungi, were observed within carbonate-filled vesicles in 46 Ma subseafloor basalt recovered during the ODP Leg 200 in the Pacific ocean. These findings imply that fungal life may possibly still exist in the subseafloor basaltic environment.

Hydrothermal fluids

Several studies of the microbial diversity in hydrothermal fluids (see *Hydrothermal Environments, Marine*) associated with eruptions in the central volcanic active zone of spreading ridges have been carried out during the last years (Summit and Baross, 1998, 2001; Huber et al., 2002, 2003). These studies have shown that the vent fluids inhabit microorganisms that are different from indigenous seawater microorganisms, suggesting that the vent fluids carry endolithic microbial cells from the basaltic subsurface environment. In the studies by Huber et al. (2002, 2003) dominant subseafloor phylotypes affiliated with the *Alpha*-, *Gamma*-, *Delta*- and *Epsilon-proteobacteria*, *Firmicutes*, novel candidate divisions, Group I *Crenarchaeota*, and Group II *Euryarchaeota* were detected. Most of these phylotypes were reported to be unique, differing from those of surrounding seawater, and affiliated with both low- and high-temperature groups. Considerable overlap with seawater was only found within *Alpha*- and *Gamma-proteobacteria*. To explain the retrieved diversity, Huber et al. (2003) proposed a schematic model of the basaltic subseafloor at the sampling site, based on hydrothermal fluid and seawater mixing that included three different compartments: a deep, anaerobic zone dominated by the hot hydrothermal fluid that contains mostly thermophilic microorganisms; an intermediate zone with both seawater and hydrothermal fluid and the highest variability in microbial community composition, probably including anaerobes, aerobes, and microaerophilic organisms; and an uppermost low-temperature, aerobic zone that is seawater-dominated, possibly containing seawater organisms. Unique subseafloor microorganisms flushed out from this uppermost zone by the vent water could thus be similar to microorganisms detected in nonhydrothermal basalts. Some of the *Gamma*- and *Epsilon-proteobacteria* sequences retrieved from both nonhydrothermal seafloor and subseafloor samples (Lysnes et al., 2004a, b) were phylogenetic affiliated

to sequences retrieved from the $<50^{\circ}\text{C}$ diffuse flow vent fluids associated with an eruptive event on the Juan de Fuca Ridge (Huber et al., 2003).

Investigation of 65°C subsurface fluids from aging (3.5 Ma) ocean crust by Cowen et al. (2003) also demonstrated the presence of a diverse bacterial and archaeal community in hydrothermal active areas of the mid-ocean ridge flanks. In this reduced, hydrothermal environment DNA sequences related to the ammonia-producing *Ammonifex degensii* and sulfate reducers of the *Delta-proteobacteria*, the low G + C Gram-positive genus *Desulfotomaculum*, and *Archaea* (*Archaeoglobus*) were dominant. A later study of 20°C subseafloor fluids from the same area demonstrated that the microbial community in the fluids composed of species indigenous to the subseafloor, as well as species from seawater and sediments (Huber et al., 2006). No sequences retrieved from nonhydrothermal seafloor and subseafloor basalts resembled those obtained from these 65°C subseafloor fluids.

Using available published 16S rDNA sequences from basalt, hydrothermal fluids, basalt enrichments, and data from other relevant environments, Mason et al. (2007) examined the phylogenetic diversity of microbial communities associated with marine basalts. Based on these data, it was suggested that the microorganisms have a cosmopolitan distribution. Most groups were found in both basalts and sediments, but are distinct from microbes in other marine habitats. One group of Marine Group I *Crenarchaeota* seems furthermore to be specifically adapted to basalt.

Biosignatures in ophiolites and greenstone belts

During the last years, terrestrial fragments of ancient ocean crust (ophiolites) and greenstone belts have been investigated for similar biosignatures as those observed within in situ oceanic basalt. For example, the results from the well-preserved ~ 90 Ma Troodos ophiolite in Cyprus revealed comparable traces of microbial life in the glassy lava margins as reported from studies of in situ oceanic crust, except for DNA that could not be detected by specific staining (Furnes et al., 2001c). This, together with geochemical and isotope data indicative of seawater alteration under oxidizing condition, imply that the main fraction of the alteration occurred prior to obduction during an early stage of ocean-floor alteration. Comparable textural, geochemical, and isotopic data obtained from lava margins from the ~ 3.5 billion-year-old Barberton greenstone Belt in South Africa further suggest subaqueous microbial activity during the early history of the Earth (Furnes et al., 2004) (see *Early Earth*). Thus, these biosignatures could be of great relevance in the search for life elsewhere in the universe (see *Astrobiology*).

Conclusions

Endolithic microbial communities have been documented in glassy margins of seafloor and subseafloor basaltic lavas from various locations of the ocean crust. In seafloor

basalt the microbial cells are easily recognized by electron microscopy, and are shown to be closely associated with the alteration of the glass. In subseafloor basalt the microbial activity has mainly been recognized by the use of biosignatures such as characteristic cell-like alteration textures in the glass, elevated concentrations of carbon and nitrogen in these textures, and stable carbon isotope ratios of disseminated carbonate consistent with biological processes. DNA-specific staining indicates the presence of DNA in the cell-like alteration textures. Culturing and biomolecular studies have revealed the existence of diverse, endolithic microbial communities in the glassy margins of oceanic lavas. The results suggest that iron and manganese cycling are important microbial processes in cold, nonhydrothermal regions, while sulfur cycling plays a major role at elevated temperatures in hydrothermal active areas. The endolithic microbial life in oceanic basalt may have a significant impact on the alteration of the basalt and the chemical exchange between the ocean crust and seawater.

Definition

Beggiatoa is a colorless, sulfur-storing bacterium belonging to the Gammaproteobacteria, filamentous, motile, and not attached.

Bacteria of the genus *Beggiatoa* live by the oxidation of sulfide with oxygen or nitrate. They are benthic

Beggiatoa, Figure 1 *Beggiatoa* filaments of 6 μm diameter seen under the light microscope with dark field illumination. The sulfur globules reflect the light and give the filaments their shining white appearance.

organisms, which occur in almost all freshwater and marine environments where sulfide is present, e.g., wastewater, areas of coastal upwelling, salt marshes, hydrothermal vents, cold seeps, methane hydrates, etc. In contrast to most bacteria, *Beggiatoa* can be recognized by its typical morphology. It is a filamentous bacterium, which is motile by gliding and stores elemental sulfur inside, giving it a shining white appearance (Figure 1). The filaments can be several millimeters to centimeters long and are formed by long rows of cells with diameters between 1 and 200 μm . The larger species of *Beggiatoa* (>5–10 μm in diameter) have a central vacuole, which they use for storing nitrate in high concentrations (ca 10–300 mM).

Beggiatoa filaments typically occur as mats on top of the sediment or within the upper few centimeters. They actively glide to the overlapping zone of oxygen, supplied from the open water, and sulfide evolving in the sediment. In addition to oxygen, the larger species can also use internally stored nitrate for the oxidation of sulfide and thereby increase their rates of sulfide oxidation or survive periods of anoxia. Sulfide is first oxidized to sulfur, which forms intracellular sulfur globules, and then further on to sulfate. If sulfide concentrations are high, the cells are filled with many sulfur globules, which are disappearing in the absence of sulfide. Apart from sulfur and nitrate, *Beggiatoa* filaments were also observed to store polyphosphate and poly-beta-hydroxybutyrate (PHB).

Biodeterioration: Undesirable alteration of the properties of materials caused by vital activities of organisms.

Introduction

Materials are exposed to weathering processes caused by physical, chemical, and biological factors, leading to an irreversible loss of our cultural heritage. The reduction of decay by conservation strategies is of particular importance to protect historical monuments or significant cultural artifacts.

Generally, the velocity of decay depends on the chemical nature and physical structure of materials as well as external factors associated to the locations where the objects are exposed. In many studies it was demonstrated that the process of weathering consists of various mechanisms acting together in coassociation with more or less intensity, making it impossible to separate individual aspects such as physical, chemical, or biological factors from each other (Koestler et al., 1994; Ehrlich, 2002). In many cases microbial activities can accelerate or trigger physicochemical processes. But the composition of microbial consortia, rather the microbial activity, is also affected by the surrounding chemical and physical factors.

Solar irradiation, wind, and variations in temperature and humidity predominate the physical effects. Wind and humidity, of course, lead to the erosion of particles from stone surfaces. Variations in temperature, due to diurnal and seasonal changes, cause tensile stresses that can break up the structure of the material, resulting in a loss of persistence. Humidity, in combination with frost and salt, can intensify this effect. The crystallization of water or saline solutions is connected with an increase in volume that leads to “frost shattering” or “saline shattering” (Steiger and Dannecker, 1995).

Chemical weathering may be caused by rain water which dissolves carbon dioxide originating from the ambient air or from respiration of present microorganisms. Generated carbon acid reacts with calcium carbonate, thereby producing calcium hydrogen carbonate with a higher solubility than calcium carbonate (Bell, 1993).

According to Krumbein and Schönborn (1987), biological damages of building material can be divided into

different categories: (1) Anthropogenically induced damages due to atmospheric pollution as a result of the industrialization. These processes lead to an increasing level of inorganic (SO_2 , NO_x) and organic (aliphatic and aromatic hydrocarbons) compounds in the air. This implicates acid rain that has a corrosive effect on stone buildings or other exposed materials (Pitzurra et al., 2003; Winkler, 1987). (2) Damages caused by higher plants and animals. The growth of higher plants, for example, leads to the physical destruction of materials. Moreover, excrements of birds contain ammoniac and nitrite, which can be utilized by chemolithotrophic bacteria. (3) Microorganisms such as bacteria, algae, fungi, and lichens can cause a degradation of materials. These damaging effects will be specified below.

Furthermore, biological colonization and the intensity of associated biodeterioration processes are strongly influenced by water availability. This is determined by specific material parameters such as porosity and permeability, as well as by environmental conditions.

Microbial degradation processes

How do microbial associations interact within these complex weathering processes? A considerable amount of studies have been done to figure out the role of microbiological agents in weathering processes (e.g., Urzi and Krumbein, 1994; Griffin et al., 1991; Warscheid and Braams, 2000). Generally, microorganisms play an important role within the regulation of the global cycles of materials, contributing to the function of the ecosystems. However, microorganisms also play a crucial role concerning the stability of materials. The interactions between microbial associations and materials can be divided into three different categories (Weber, 1993, cf. Figure 1): (1) The material can be decomposed enzymatically and used as a nutrient source by microbial associations. (2) Microorganisms can excrete metabolic compounds such as inorganic and organic acids that interact with mineral compounds of the material, thus causing dissolution and discoloration. (3) The material can be damaged by physical (mechanical) forces due to the growth of microorganisms.

For the most part, microorganisms conglomerate to biofilms of different natures such as crusts, fluffs, or slime, giving them the ability to colonize nearly all biotic and abiotic surfaces (Costeron et al., 1987). Biofilms can exhibit a highly spatial structured composition (Stoodley et al., 2002), thereby consisting of different prokaryotic and/or eukaryotic populations, extracellular polymeric substances (EPS), accumulated polyvalent cations, as well as solvated and dissolved organic and inorganic particles. The formation of biofilms provides considerable advantages including mechanical stability, the facility of symbiotic and syntrophic interactions, the building of a diffusion barrier and an increased resistance against toxic environmental conditions, biocides, aridity, or pH variabilities (Wolfaardt et al., 1999). However, the presence of biofilms can lead to biophysical determined damages of

oxygen ligands. Stoichiometry and temperature dependence of the metal–bacteria adsorption reactions can also be extracted using this approach (Gorman-Lewis et al., 2006).

Summary

Microbial–metal adsorption includes the electrostatic and chemical association of metals with the organic functional groups of microbial cell surfaces. This can be considered a passive process driven by the electronegativity of the microbial cell wall/EPS and the Gibbs free energy of the adsorption reactions. These adsorption reactions seem to be dominated by binding of cations to the oxygen containing moieties on the cell surface. Future advances in elucidating the mechanisms of metal adsorption to microbes will come from combining novel analytical techniques, such as colorimetry and spectroscopy, with bulk partitioning studies and site-specific adsorption models.

Definition

Destruction of rocks and minerals by biological activities has been termed bioerosion (Neumann, 1966). It includes mechanical as well as chemical effects, that is, bioabrasion and biocorrosion (Schneider, 1976; Golubic and Schneider, 1979). However, both the processes often co-occur; they are functionally interconnected and mutually supportive. Biocorrosion can result from the activity of macro- or microorganisms and, thus, is called macrobiocorrosion and microbiocorrosion. Microbiocorrosion can also be closely associated with microbial rock formation and consolidation in stromatolitic structures (Reid et al., 2000; Macintyre et al., 2000; Garcia-Pichel et al., 2004; Dupraz and Visscher, 2005). In fact, the oldest known fossils of microboring organisms were located in lithified horizons of silicified stromatolites (Zhang and Golubic, 1987).

MICROSENSORS FOR SEDIMENTS, MICROBIAL MATS, AND BIOFILMS

Dirk de Beer

Max Planck Institute for Marine Microbiology, Bremen, Germany

Synonyms

Amperometry; Diagenesis; Diffusion-reaction; Micro-electrode; Microenvironment; Potentiometry

Definition

Microsensors are needle-shaped sensors ([Figure 1](#)) that can be inserted in biologically active matrices, such as sediments, to measure directly concentrations of certain compounds.

Introduction

In sediments, microbial mats, and biofilms steep gradients of substrates and products develop, due to high metabolic activities and mass transfer limitations (see Chapters [Biofilms](#); [Microbial Mats](#); [Sediment Diagenesis – Biologically Controlled](#)). Stratifications of microenvironments develop that determine the existence and activity of microbial consortia. For example, in active biofilms oxygen can penetrate less than 50 μm (de Beer et al., 1994c; de Beer et al., 1993), in sediments oxygen penetrates typically less than 2 mm (de Beer, 2001; Jørgensen and Revsbech, 1985; Meyers et al., 1987; Revsbech,

Microsensors for Sediments, Microbial Mats, and Biofilms, Figure 1 Left panel, microsensors for oxygen (left sensor), for pH (middle), and for H_2S (right sensor). The right panel zooms further in on the tip of an oxygen sensor, showing the gold-plated electrode behind a silicon membrane, the ticks on the ruler are 1 μm .

1983; Sorensen et al., 1981; Sweerts and de Beer, 1989). Below the oxic zone anaerobic microbial processes can occur, such as denitrification and sulfate reduction (see Chapter [Sulfur Cycle](#)), that determine the element cycling (the coupled degradative and chemolithotrophic processes) in the system as a whole. Stratifications on such a small scale cannot be studied by more classical techniques such as pore-water extraction and chemical analyses. Extraction is impossible on such small scales, as it is highly destructive for the system and concentrations will have changed during the extraction procedure. To study such stratified systems we need microsensors that are minimally invasive and directly measure the concentrations without disturbing the system in which we measure. Moreover, as the system is not disturbed by microsensor analyses, we can perform sequences of measurements and, for example, study how the system responds to environmental changes. Microsensor measurements have enormously enhanced the insight in the vertical distribution of microbial processes in sediments. Microsensors were originally developed for physiological studies in animal and plant tissues, and even for intracellular measurements (Ammann, 1986; Hinke, 1969; Thomas, 1978), but soon applied in environmental studies (Bungay et al., 1969). They became an established technique for ecological studies by the developing work of Revsbech, who made them more robust and invented a large diversity of sensors (Kühl and Revsbech, 2000; Revsbech and Jørgensen, 1986).

Biodeterioration: Undesirable alteration of the properties of materials caused by vital activities of organisms.

Introduction

Materials are exposed to weathering processes caused by physical, chemical, and biological factors, leading to an irreversible loss of our cultural heritage. The reduction of decay by conservation strategies is of particular importance to protect historical monuments or significant cultural artifacts.

Generally, the velocity of decay depends on the chemical nature and physical structure of materials as well as external factors associated to the locations where the objects are exposed. In many studies it was demonstrated that the process of weathering consists of various mechanisms acting together in coassociation with more or less intensity, making it impossible to separate individual aspects such as physical, chemical, or biological factors from each other (Koestler et al., 1994; Ehrlich, 2002). In many cases microbial activities can accelerate or trigger physicochemical processes. But the composition of microbial consortia, rather the microbial activity, is also affected by the surrounding chemical and physical factors.

Solar irradiation, wind, and variations in temperature and humidity predominate the physical effects. Wind and humidity, of course, lead to the erosion of particles from stone surfaces. Variations in temperature, due to diurnal and seasonal changes, cause tensile stresses that can break up the structure of the material, resulting in a loss of persistence. Humidity, in combination with frost and salt, can intensify this effect. The crystallization of water or saline solutions is connected with an increase in volume that leads to “frost shattering” or “saline shattering” (Steiger and Dannecker, 1995).

Chemical weathering may be caused by rain water which dissolves carbon dioxide originating from the ambient air or from respiration of present microorganisms. Generated carbon acid reacts with calcium carbonate, thereby producing calcium hydrogen carbonate with a higher solubility than calcium carbonate (Bell, 1993).

According to Krumbein and Schönborn (1987), biological damages of building material can be divided into

different categories: (1) Anthropogenically induced damages due to atmospheric pollution as a result of the industrialization. These processes lead to an increasing level of inorganic (SO_2 , NO_x) and organic (aliphatic and aromatic hydrocarbons) compounds in the air. This implicates acid rain that has a corrosive effect on stone buildings or other exposed materials (Pitzurra et al., 2003; Winkler, 1987). (2) Damages caused by higher plants and animals. The growth of higher plants, for example, leads to the physical destruction of materials. Moreover, excrements of birds contain ammoniac and nitrite, which can be utilized by chemolithotrophic bacteria. (3) Microorganisms such as bacteria, algae, fungi, and lichens can cause a degradation of materials. These damaging effects will be specified below.

Furthermore, biological colonization and the intensity of associated biodeterioration processes are strongly influenced by water availability. This is determined by specific material parameters such as porosity and permeability, as well as by environmental conditions.

Microbial degradation processes

How do microbial associations interact within these complex weathering processes? A considerable amount of studies have been done to figure out the role of microbiological agents in weathering processes (e.g., Urzi and Krumbein, 1994; Griffin et al., 1991; Warscheid and Braams, 2000). Generally, microorganisms play an important role within the regulation of the global cycles of materials, contributing to the function of the ecosystems. However, microorganisms also play a crucial role concerning the stability of materials. The interactions between microbial associations and materials can be divided into three different categories (Weber, 1993, cf. Figure 1): (1) The material can be decomposed enzymatically and used as a nutrient source by microbial associations. (2) Microorganisms can excrete metabolic compounds such as inorganic and organic acids that interact with mineral compounds of the material, thus causing dissolution and discoloration. (3) The material can be damaged by physical (mechanical) forces due to the growth of microorganisms.

For the most part, microorganisms conglomerate to biofilms of different natures such as crusts, fluffs, or slime, giving them the ability to colonize nearly all biotic and abiotic surfaces (Costeron et al., 1987). Biofilms can exhibit a highly spatial structured composition (Stoodley et al., 2002), thereby consisting of different prokaryotic and/or eukaryotic populations, extracellular polymeric substances (EPS), accumulated polyvalent cations, as well as solvated and dissolved organic and inorganic particles. The formation of biofilms provides considerable advantages including mechanical stability, the facility of symbiotic and syntrophic interactions, the building of a diffusion barrier and an increased resistance against toxic environmental conditions, biocides, aridity, or pH variabilities (Wolfaardt et al., 1999). However, the presence of biofilms can lead to biophysical determined damages of

Biodeterioration (of Stone), Figure 1 Interactions between materials, environmental conditions, and subaerial biofilms include (1) atmosphere substrate interactions (2) interactions between atmosphere and biofilms (3) interactions of metabolic compounds and substrate; enzymatic degradation (4) physicochemical interactions between biofilm and substrate (5) physical forces due to microbial growth.

surface structures of stone (Gorbushina and Krumbein, 2000; Gorbushina, 2007). Variations in temperature and humidity induce shrinking and swelling cycles of the film, leading to an alteration of hydrophobic–hydrophilic properties of rock surfaces. As a consequence, hydrophobic properties of stone surfaces can turn into hydrophilic.

Microorganisms involved in biodeterioration processes

The ecology of microbial associations colonizing rocks is highly complex and involves different groups of microorganisms with different physiological properties. These ecosystems can develop in various ways, depending on environmental conditions and physicochemical properties of the material. Therefore, only a small range of examples can be discussed in this framework, representing the complexity of the interactions between microorganisms and their substrate.

Phototrophic microorganisms

Phototrophic microorganisms such as algae, cyanobacteria and lichens, but also mosses and even higher plants cover stone surfaces, thus changing the face of new buildings or cultural heritage. In many cases they form biofilms or crusts to protect themselves from unfavorable environmental factors. These crusts or films can appear in a deep or light green color under humid conditions or in black tint under dry environmental conditions (Urzi and Krumbein, 1994; Krumbein and Warscheid, 1992). Under particular

climatic conditions (e.g., tropical environments) these biofilms provide a protective effect, isolating the stone surface from aggressive environments and regulating humidity and temperature (Krumbein and Warscheid, 1992). But the formed biopatina can also cause damages by physical and chemical processes (Krumbein and Warscheid, 1992; De los Rios et al., 2009). Associated biodeterioration processes can be induced by the excretion of corrosive acids (Arino et al., 1997), the uptake of substrate compounds such as sulfur and calcium and accumulation into their cells (Orgenta Calvo et al., 1994), and by the alteration of stone forming minerals (Ortega-Morales et al., 2000; Crispim and Gaylarde, 2004). Finally, the penetration of hyphae and roots causes enlargement of pores and loosening of stone particles from the material (Ascaso et al., 1998). The formation of biofilms intensifies this loss of structural consistency (Orgenta-Calvo et al., 1991).

Due to the capability of fixing atmospheric nitrogen, phototrophic organisms are often the primary settlers of habitats especially in combination with fungi as lichens. In rural or strongly industrialized areas where the air is enriched with nitrogen from fertilizers or industrialization, their growth can be enhanced (Cadot-Leroux, 1996; Cicek et al., 2008). Some phototrophic microorganisms (epilithicphototrophs) may penetrate several millimeters into the stone pore system (Golubic et al., 1981). Additionally, some of these microorganisms can colonize extreme locations, whereby a special pigmentation protects them against strong light irradiation (Krumbein and Jens, 1981).

Chemolithotrophic and chemoorganotrophic microorganisms

Even the natural biomass accumulated by photosynthetic microorganisms – especially in combination with anthropogenic pollution – can serve as nutrient source for the establishment of heterotrophic microorganisms (Warscheid et al., 1991; Zanardini et al., 2000).

Besides, even without a primary settlement of phototrophic microorganisms an establishment of heterotrophic organisms is possible (Krasilnikov, 1949). A sufficient amount of inorganic compounds (e.g., sulfur, ammonium, sulfide) enables the appearance of chemolithoautotrophic bacteria (Kaufmann, 1960; Pochon and Jaton, 1967). The formation of nitrous acid (HNO_2 by *Nitrosomas*) or nitric acid (HNO_3 by *Nitrobacter*) and sulfuric acid (H_2SO_4 , *Thiobacillus*) results in the solution of mineral rock compounds. Acidic metabolic compounds resulting from the oxidation of sulfur, for example, interact with calcium carbonate of the stone structure. This reaction leads to the formation of calcium sulfate, which is more soluble than calcium carbonate.

The most numerous microorganisms in natural building stone are chemoorganotrophic bacteria. Results of Warscheid et al. (1993) indicate that they colonize natural stone within weeks. They can excrete acid compounds but, generally, their destructive activity has been evaluated as low (Lewis et al., 1988). Nevertheless, they are extensively involved in the formation of biofilms, thus causing physicochemical properties of the mineral structure described above. Materials can contain or be associated with organic compounds such as dust, natural resin, wax, or atmospheric aerosols that can act as nutrient source for chemoorganotrophic microorganisms (Warscheid, 1990). As an effect of organic pollution, chemoorganotrophic microorganisms can be the first settlers on buildings in highly industrialized locations (Krumbein, 1966). Many chemoorganotrophic bacteria are able to use low degradable compounds, offering nutrients for other microorganisms of the microbial consortia (Warscheid et al., 1991; Zanardini et al., 2000).

Fungi

The colonization of stone surfaces or other materials by fungi causes damages, especially by physical (mechanical) forces (cf. Figure 2). The formation of penetration hyphae enables some fungi to enter actively into materials, despreding within the material and affecting the so-called biopitting structures on rock surfaces (Sterflinger and Krumbein, 1997). Furthermore, the production of aggressive acidic metabolites leads to biocorrosion (Kurakov et al., 1999). In comparison to bacteria, fungi can establish rapidly, especially in environments with low humidity due to their widespread system of hyphae (Weber, 1993). Their damaging effects also include the discoloration of surfaces due to the building and excretion of melanins (Gorbishina et al., 1993). The synthesis of special pigments such as melanin, carotenoids, and mycosporines provides

Biodeterioration (of Stone), Figure 2 (a) Scanning electron microscopic demonstrate colonization of amber surface by recent microorganisms. Fungal hyphae cover the amber surface and accumulate in cracks leading to loss of material persistence by physical stresses; scale bar 100 μm . (b) closeup, scale bar 10 μm . (Reitner and Beimforde, 2008).

protection against UV radiation and enables some species (e.g., black fungi) to colonize even at locations with extreme UV radiation (Chertov et al., 2004).

Measures and preventive treatments

In general, a microbial colonization is primarily dependent on the availability of water and nutrients and specific material parameters such as porosity, permeability, architectural conditions (considering buildings), and environmental factors. Natural selective processes can lead to the formation of populations that reveal a perfect adaption between organisms, substrate, and environment. A previous individual and comprehensive analysis of all factors and relationships is essential before preventive treatments or cleaning of the material is applied. A mechanical cleaning of historical buildings from dust or biological films should integrate a chemical analysis to characterize the surface dirt. Otherwise, the cleaning procedure can fail to have a long-lasting effect and even accelerate the degradation processes or alteration within the composition of microbial associations affecting changes of microbial activity (Dornieden et al., 2000).

Water cleaning can help remove soluble salts and biological infections, but in the long term it can lead to a wider dispersion of the microbial infection because of increased humidity. Furthermore, consolidation treatments can be applied, but their effectiveness is strongly connected to the physical structure of the stones. The application on stone surfaces with insufficient consistence and absorbent capacity can intensify physical damages (Sattler, 1992; Wendler, 1992; Zoghalmi and Gómez-Gras, 2004). Other preventive agents impregnate surface structures and are often based on high polymer polysaccharide, silane, or siloxane. Various studies have shown that the application of consolidants or water repellents induce an increasing activity or colonization of microorganisms using these restoration agents as nutrient source (Krumbein et al., 1993; Petersen et al., 1991, cf. Figure 3). Studies of Urzi and

De Leo (2007) and De Leo and Urzi (2003) have shown that water repellents alone do not stop microbial colonization, but in combination with biocides, microbial growth can be prevented.

Finally, it is important to mention that the treatment with biocides should only be applied in instances where biodeterioration processes cannot be controlled and chemical applications are unavoidable. An inappropriate treatment with biocides or other preventive arrangements can lead to an increasing selective microbial colonization that may accelerate the deterioration.

Summary

The process of weathering consists of physical, chemical and biological factors acting together with more or less intensity, leading to an irreversible loss of our cultural heritage. Microbial activities can accelerate or trigger physicochemical processes. But the composition of microbial community or rather the microbial activity is also affected by the surrounding chemical and physical factors. Interactions between microbial associations and materials contain the enzymatic decomposition of materials, excretion of metabolic compounds such as inorganic or organic acids, and damages by physical (mechanical) forces due to the growth of microorganisms.

Definition

Bioerosion is defined as erosion, i.e., removal and transport of materials by the action of organisms. Bioabrasion refers to removal by mechanical means: scraping, rasping, drilling. Biocorrosion refers to removal by chemical means: etching, dissolving, boring. Bioerosion is often carried out by a combination of bioerosional tools. Bioerosion by microorganisms is referred to as microbioerosion as opposed to macrobioerosion performed by animals and plants. External bioerosion is carried out by organisms that live outside the substrate but remove it in the process of seeking food (grazing). Internal bioerosion is carried out by organisms that excavate the substrate for shelter and live inside as endoliths. They penetrate the substrate actively as euendoliths, or

occupy existing cavities as cryptoendoliths or fissures in the rocks as chasmoendoliths.

Concept of bioerosion

The concept of erosion is usually discussed in geology, particularly in geomorphology, sedimentology, and soil sciences, in reference to degradation and transport of rocks and sediments by environmental forces such as wind, water, or ice. The participation of organisms in these processes and their long-term geological impact are often ignored. The role of organisms in sediment stabilization, organization, and buildup is becoming increasingly recognized as biosedimentation, and so is bioerosion, i.e., the participation of organisms in destruction of rocks and sediments.

Similar to weathering and erosion by environmental forces, the destruction of hard substrates by organisms, i.e., biological erosion or bioerosion (Neumann, 1966) includes two mechanisms: (a) biological corrosion, which refers to destruction of substrates by chemical means introduced by organisms, thus promoting dissolution of solid substrates, and (b) biological abrasion, which refers to mechanical destruction and removal of substrate by organisms (Golubic and Schneider, 1979). Sediment particles are frequently produced during biological abrasion and are redeposited (Neumann, 1966; Schneider and Torunski, 1983).

Bioerosion affects various substrates, most commonly the relatively soluble ones such as carbonates, phosphates, and sulfates. Bioerosion of siliceous rocks occurs at much lower rates and is rarely conspicuous. The objects of bioerosion include solid rocks, sediment particles, and mineralized skeletons of various live and dead organisms. Bioerosion takes place in a wide variety of aquatic and terrestrial environments. Its effects are especially noticeable in coastal carbonate rocks, coral reef structures, and molluscan calcareous skeletons, but are less apparent in skeletons of live corals (Le Campion-Alsumard et al., 1995a), encrusting coralline algae (Pantazidou et al., 2000; Tribollet and Payri, 2001; Ghirardelli, 2002), foraminifera (Golubic et al., 1984), calcareous ooid sand particles (Al-Thukair and Golubic, 1991), and fish teeth (Underwood et al., 1999).

Many researchers describe penetration into hard substrate as boring activity, in contrast to burrowing, which describes digging into loose substrate such as sand and mud; however, some use the term burrowing for penetrating any substrate. Others suggested that activities of bioeroding organisms be distinguished on the basis of their objectives (e.g., food vs. shelter). Many bioeroding organisms are fully or partially embedded in the rocky substrate, occupying an endolithic habitat, while others erode the substrate from outside. Accordingly, they have been distinguished as internal versus external bioeroders. Many investigators view bioerosion as behavior (Boucot, 1990) and relate bioeroding organisms to the traces they leave in modern and ancient hard substrates. Researchers

Synonyms

Eubacteria (term abandoned)

Definition

Prokaryotes that constitute, besides Archaea and Eukarya, a domain of life. According to (old Greek) bakterion “small rod.”

History

During the nineteenth century, several fundamental discoveries defined the beginning of modern microbiology (cf. Schlegel, 1999). Louis Pasteur (1822–1895) found that growth of bacteria in nutrient broths is not due to spontaneous generation and that fermentation is caused by the growth of microorganisms. Ferdinand Cohn (1828–1898) could state that bacteria must belong to a phylogenetic group separated from other unicellular plants or animals, due to their size, shape, the mode of cell division, and their metabolic properties. Robert Koch (1842–1910) developed the concept of infectious diseases. The final proof that bacteria must be distinct from plants and animals could be shown not until the distinct compartmentation of bacterial cells was noticed by electron microscopy, in the 1960s. Especially, the absence of a nuclear membrane was a clear indicator for some fundamental differences in cellular processes. Hence, the term “prokaryote” for bacteria (including Archaea) was introduced. The separation of *Archaea* from Bacteria (as phylogenetic groups) was achieved by Woese and Fox (1977).

Besides the missing nuclear membrane as a common cytological feature, Bacteria and Archaea are structurally and physiologically distinct. The Bacteria are the phylogenetically most diverse domain, with a rapidly growing number of phyla. Currently, more than 80 phyla could be identified (Pace, 2009). About two-third of these phyla are just represented by rDNA sequences from environmental samples. Twenty-five phyla are represented by known species. Among them, twelve phyla contain the majority of currently known and well-characterized species. The well-known representatives of phyla, however, stand for an incomplete and subjective view on the bacterial domain. Human pathogenic species are, for example, overrepresented, because of their importance for human medicine. The significance of several groups relevant for environmental processes, such as Planctomycetes or the *Roseobacter* clade has just been addressed recently. General knowledge on the physiology of these groups is still limited. Most in-depth analyses on microbial physiology and molecular biology has been performed with selected species from a small number of phyla, such as *Escherichia coli*, *Salmonella*, and *Pseudomonas* species (Proteobacteria) or *Bacillus* (Firmicutes). Some organisms like *Ralstonia* (an aerobic hydrogen oxidizing Proteobacterium) or *Rhodobacter* (a photosynthetic bacterium) are model organisms for environmentally relevant processes.

The phylogenetic tree (Figure 1), based upon 16S-rDNA data shows an overview of these major, well-characterized lineages (Cole et al., 2009; Madigan et al., 2009). In-depth analysis based upon whole genomes may allow, in future, a more accurate positioning of genes and organisms in phylogenetic trees (Ciccarelli et al., 2006; Wu and Eisen, 2008). Though the major phyla have been confirmed, some repositioning may be necessary. Some reports imply that Firmicutes are descendants of

Bacteria, Figure 1 Phylogenetic tree of Bacteria, derived from 16S rDNA sequences. (Redrawn after Madigan et al., 2009.)

the stem group, other than expected from rDNA analysis (Ciccarelli et al., 2006).

In the following chapter, a short survey on the hitherto well-investigated groups will illustrate the metabolic diversity of the organisms. Terms denoting defined phyla are capitalized.

Diversity in phylogenetic lineages

Important metabolic key processes are unique to bacteria and have just been overtaken by endosymbiosis to eukaryotes, such as chlorophyll-dependent photosynthesis and mitochondrial respiration. Thus, metabolism in every eukaryote is based upon bacterial metabolism. Eukaryotes, however, received just a small range of the highly various metabolic features from bacteria. Virtually, every reduced organic compound and numerous reduced inorganic molecules can be oxidized in a bacterial metabolism that may be either respiratory, that is, generating a membrane potential, driven by an electron flow toward an oxidized acceptor (oxygen, nitrate, and others) or fermentative (generation of ATP independent of a membrane potential). These metabolic features are unsuitable to discriminate between large groups because they are mostly not specific for only one phylum (Tables 1–4; Schlegel and Jannasch, 2006; Zinder and Dworkin, 2006). Some strategies and bacterial life-styles are, however, suitable to discriminate between certain subgroups within a phylum. In the following, some key features that may be confined to the respective groups are specified. The groups are assigned to phyla according to the “classical” phylogenetic scheme, obtained by

16S-rDNA sequence analysis (Cole et al., 2008; cf. Madigan et al., 2009).

Ancient phyla

Several representatives of the ancient bacterial groups clustering deep in the phylogenetic tree are hyperthermophilic, some of them are chemolithotrophs. The hyperthermophilic genus *Aquifex* is an obligately hydrogen oxidizing, microaerophilic, chemolithotrophic (see *Chemolithotrophy*) bacterium (Huber and Eder, 2006). The fixation of carbon dioxide does not depend on the Calvin cycle (ribulose biphosphate carboxylase as key enzyme), like in further derived phyla and green plants, but, instead, on a reversed citrate cycle. The organisms are not capable to grow on organic molecules, that is, they are obligate chemolithotrophs utilizing molecular hydrogen or reduced sulfur compounds as electron donors, at optimum growth temperatures of 85°C. Thus, the environmental conditions for the ecological niche of *Aquifex* are equivalent to the reducing conditions of the earth’s early atmosphere. The related genera *Hydrogenobacter* and *Thermocrinis* share most of *Aquifex*’ properties, but are aerobic and also utilize organic compounds.

Several important cellular features that are found in most bacterial phyla are already present in this ancient lineage: the cytoplasmic membrane is surrounded by another membrane of lipid bilayer type (outer membrane). Thus, the membranes enclose an additional compartment, the periplasmic space. The periplasmic space contains the rigid murein (peptidoglycan) sacculus. Another feature found in all, including the most ancient bacterial phyla is the bacterial flagellum (Figure 2a). Though analogous

Bacteria, Table 1 Groups of chemolithotrophic bacteria (After Schlegel and Jannasch, 2006, with modifications)

Typical species	Lineage	Metabolic process	Electron donor	Electron acceptor	Product
<i>Aquifex</i>	Aquificales	Hydrogen oxidation	H ₂	O ₂	H ₂ O
		Sulfur oxidation	S ₂ O ₃ ²⁻ , S ₀	O ₂	SO ₄ ²⁻
<i>Ralstonia eutropha</i>	Beta-Proteobacteria	Hydrogen oxidation	H ₂	O ₂	H ₂ O
<i>Pseudomonas carboxydovorans</i>	Gamma-Proteobacteria	CO oxidation	CO	O ₂	CO ₂
<i>Nitrosomonas europaea</i>	Beta-Proteobacteria	Ammonium oxidation	NH ₄ ⁺	O ₂	NO ₂ ⁻
<i>Nitobacter</i>	Alpha-Proteobacteria	Nitrite oxidation	CO ₂	O ₂	NO ₃ ⁻
<i>Thiobacillus thiooxidans</i>	Beta-Proteobacteria	Sulfur oxidation	H ₂ S, S ₀	O ₂	SO ₄ ²⁻
<i>Thiobacillus ferrooxidans</i>	Beta-Proteobacteria	Iron oxidation	Fe ²⁺	O ₂	Fe ³⁺
<i>Beggiatoa alba</i>	Gamma-Proteobacteria	Sulfur oxidation	H ₂ S, S ₀	O ₂ , NO ₃ ⁻	SO ₄ ²⁻ , N ₂
<i>Acetobacterium woodii</i>	Firmicutes	Acetogenesis	H ₂	CO ₂	Acetate

Bacteria, Table 2 Groups of phototrophic bacteria (After Schlegel and Jannasch, 2006, with modifications)

Bacterial group	Lineage	Key genus	Chemoorganotrophic growth	Electron donors for photosynthesis
Purple non-sulfur bacteria	Alpha-/beta-Proteobacteria	<i>Rhodospirillum</i>	+	H ₂ , organic, (S ²⁻)
Purple sulfur bacteria	Gamma-Proteobacteria	<i>Chromatium</i>	—	S ²⁻ , S ⁰ , S ₂ O ₃ ²⁻ , H ₂
Green sulfur bacteria	Chlorobi	<i>Chlorobium</i>	—	S ²⁻ , S ⁰ , S ₂ O ₃ ²⁻ , H ₂
<i>Chloroflexus</i> group	Chloroflexi	<i>Chloroflexus</i>	+	Organic (S ²⁻)
Heliobacteriaceae	Firmicutes	<i>Heliobacterium</i>	—	Organic
Aerobic phototrophic Proteobacteria	Alpha-Proteobacteria	<i>Roseobacter</i>	—	Organic
Cyanobacteria	Cyanobacteria	<i>Synechococcus</i> <i>Oscillatoria</i>	—	H ₂ O H ₂ O (S ²⁻)

Bacteria, Table 3 Bacterial groups and their electron acceptors for respiratory processes (After Schlegel and Jannasch, 2006, with modifications)

Physiological group	Typical species	Lineage	Respiratory process	Electron acceptor	Reduction products
Denitrifiers	<i>Pseudomonas denitrificans</i>	Gamma-Proteobacteria	Aerobic respiration nitrite respiration	O ₂ , NO ₃ ⁻	N ₂ , N ₂ O, NO ₂ ⁻
Sulfate reducers	<i>Desulfovibrio vulgaris</i>	Delta-Proteobacteria	Sulfate respiration	SO ₄ ²⁻	S ²⁻
Sulfur reducers	<i>Desulfuromonas acetoxidans</i>	Delta-Proteobacteria	Sulfur respiration	S ⁰	S ²⁻
Acetogenic bacteria	<i>Acetobacterium woodii</i>	Firmicutes	Carbonate respiration	CO ₂	acetate
Succinogenic bacteria	<i>Wolinella succinogenes</i>	Epsilon-Proteobacteria	Fumarate respiration	fumarate	succinate
Iron reducer	<i>Pseudomonas GS-15</i>	Gamma-Proteobacteria	Iron respiration	Fe ³⁺	Fe ²⁺

motility structures are also found in Archaea (and in Eukarya), they are phylogenetically completely unrelated. For other types of appendages (bacterial pili, Figure 2a), homologues in Archaea could be described (Szabo et al., 2007).

Thermotoga and related genera also comprise chemoorganotrophic hyperthermophilic representatives. Comparative genomics revealed that more than 20% of the *Thermotoga* genome shares strong homologies with genes from various hyperthermophilic archaeal species, accounting for an extensive inter-domain horizontal gene transfer (Nelson et al., 1999).

Chloroflexi and Chlorobi

(Bacterio)chlorophyll-dependent photosynthesis (see *Photosynthesis*) is unique for bacterial organisms (Table 2; Overmann and Garcia-Pichel, 2006). Ancestors of green nonsulfur bacteria (Chloroflexi) were very likely the first photosynthetic organisms of the bacterial domain (Oyaizu et al., 1987). The key genus *Chloroflexus* is a thermophilic representative of the group. Besides photoautotrophic growth, *Chloroflexus* is also able to use organic compounds. Carbon dioxide fixation is still Rubisco independent and is carried out by transfer of hydrogen carbonate to activated acetate and propionate

Bacteria, Table 4 Groups of fermentative bacteria

Fermentative process	Typical species	Lineage	Preferred substrates	Fermentation products (minor products)
Ethanol fermentation	<i>Zymomonas mobilis</i>	Alpha-Proteobacteria	Glucose	Ethanol (CO ₂)
Lactate fermentation – homofermentative – heterofermentative	<i>Lactobacillus casei</i> <i>Leuconostoc mesenteroides</i>	Firmicutes	Glucose, lactose Glucose, lactose	Lactate Lactate (ethanol, CO ₂)
Butyrate fermentation	<i>Clostridium butyricum</i> <i>Clostridium acetobutylicum</i> <i>Clostridium klyuveri</i>	Firmicutes Firmicutes Firmicutes	Glucose Glucose Ethanol+acetate	Butyrate (acetate, H ₂ , CO ₂) Butyrate, butanol (acetone, 2-propanol)
Homoacetate fermentation	<i>Clostridium acetivum</i>	Firmicutes	Fructose	Acetate
Propionate and succinate fermentation	<i>Propionibacterium pentosaceum</i> <i>Veillonella alcalescens</i> <i>Bacteroides ruminicola</i>	Actinobacteria Firmicutes	Sugars, Lactate Lactate Sugars	Propionate (succinate) Propionate (acetate, H ₂ , CO ₂) Propionate
Mixed acid and butanediol fermentation	<i>Escherichia coli</i> <i>Enterobacter aerogenes</i>	Gamma-Proteobacteria	Glucose, lactose Glucose	Lactate, ethanol acetate (formate, succinate, H ₂ , CO ₂) 2,3 butanediol, ethanol (formate, H ₂ , CO ₂)
Amino acid fermentation	<i>Clostridium tetanomorphum</i> <i>Clostridium sticklandii</i> <i>Clostridium oroticum</i>	Firmicutes Firmicutes Firmicutes	Glutamate Lysine Orotate	Butyrate (acetate, CO ₂ , NH ₃) Butyrate (acetate, NH ₃) Acetate (CO ₂ , NH ₃)

(acetyl-coenzyme A, propionyl-coenzyme A) in the hydroxypropionate pathway. Green sulfur bacteria (Chlorobi) represent a separate lineage of anoxygenic photosynthetic bacteria. Similar to photosynthetic Proteobacteria, the organisms use reduced sulfur compounds (H₂S, S₀) as well as organic compounds as electron donors. The organisms use a reverse citric acid cycle for carbon dioxide fixation. A remarkable structural feature, the chlorosome, consisting of densely stacked self-assembled antenna bacteriochlorophylls, is a simple but very effective light harvesting complex. This arrangement transfers light energy (excitons) effectively to the reaction centre in the cytoplasmic membrane. The organisms are, hence, adapted to very low light conditions. Chlorosome genes were transferred, by horizontal gene transfer, to some phototrophic lineages, including some genera of the *Chloroflexus* group (cf. Hanada and Pierson, 2006).

Spirochetes

Spirochetes are rather structurally than metabolically remarkable (Charon et al., 1992). The spirochete endoflagellum is of the standard bacterial type, but is located in the periplasmic space. In all other bacterial groups, the flagellum (if present) traverses all layers of the envelope. The endoflagellum is helically wound around the flexible protoplast and gives the cell its unique, helically coiled appearance. The movement of the flagellum drives the cell body in a drill-like manner. By this way, movement of the cell in highly viscous media like tissue is facilitated. In fact, numerous symbiotic and

pathogenic organisms belong to this group (*Teponema*, *Borrelia*, *Leptospira*).

Deinococcus/Thermus

Another separate lineage of extremophilic bacteria is represented by the key genera *Deinococcus* and *Thermus*. The organisms mainly oxidize carbohydrates and proteins. *Thermus* species are thermophilic and grow between 50°C and 80°C. The remarkable members of the *Deinococcus* group are adapted to desiccation and ionizing or ultraviolet radiation. The composition and thickness of the cell wall, DNA compaction, and DNA repair systems are special protective features (Da Costa et al., 2006).

Flavobacteria/Cytophaga

The Flavobacteria/Cytophaga phylum comprises diverse, mostly heterotrophic, anaerobic or aerobic bacteria (Bernardet and Nakagawa, 2006). Within this group, the members of the genus *Bacteroides* represent the dominant bacteria in the human large intestine. The second key genus *Flavobacterium* is mostly found in freshwater and marine habitats. The Acidobacteria with the genera *Acidobacterium*, *Geothrix*, and *Halophaga* are heterotrophic soil inhabitants. It is known from phylogenetic analysis of environmental DNA that uncultured members of the genera are widespread in other terrestrial and aquatic habitats and may thus play an important ecological role. Several members of *Cytophaga* and related genera are important degraders of cellulose and other polysaccharides. Cells move by gliding, a surface motility mechanism that is also observable in other bacterial lineages.

Bacteria, Figure 2 Some cytological features of bacteria. (a) The bacterial flagellum (fl) is a unique motility structure of the bacterial kingdom. The short spikelike appendages (pili) are also found in Archaea (electron micrograph of a metal shadowed *Escherichia coli* cell). (b) The corkscrew-like *Spirochete* morphology (here, *Spirochaeta thermophila*) is determined by the flagellum ("axial filament") wound around the elongate cell body. The axial filament propels the whole cell in a drill-like manner. (c) Aquatic organisms tend to form long filaments (filamentous cyanobacterium *Phormidium* sp.). Light micrograph, differential interference contrast. (d) Several filaments of the cyanobacterium *Microcoleus*, frequently found in terrestrial habitats, are surrounded by a polysaccharide sheath (green). The filaments (red) glide out of the tubelike sheath. Sheaths are found in various bacterial groups. Fluorescence light micrograph. (e) *Bacillus* mother cell with endospore. Electron micrograph of an ultrathin section. (f) Purple sulfur bacterium (*Chromatium*) with intracellular sulfur granula. Light micrograph, phase contrast.

The gliding motility of *Cytophaga* and relatives, however, is based on a unique, not yet understood, cell envelope-associated mechanism.

Planctomyces/Verrucomicrobia

The *Planctomyces/Verrucomicrobia* lineages comprise morphologically uncommon groups of uncertain phylogeny. Planctomycetes develop protein stalks as attachment structures and divide by budding (instead of binary fission, the common way of bacterial and archaeal cell division). Peptidoglycan is missing. Planctomycetes and the related phylum of Verrucomicrobia also show a highly compartmentalized cytoplasm (Lee et al., 2009). Endocytosis-like processes, a typical feature of eukaryotes, could also be observed (Lonhienne et al., 2010).

In *Gemmata* spp. the nucleoid is surrounded by an intracytoplasmic unit membrane. The anammoxosome in *Brocadia anammoxidans* is a structurally similar compartment, but appears to be involved in the compartmentation of anaerobic oxidation of ammonia, which is a unique feature of this group. The genera *Verrucomicrobium* and *Prostheco bacter* possess lobe-like cellular extensions. The organisms are mostly found in freshwater habitats. The lobed appendages increase the cell surface and facilitate the uptake of substrate molecules in an oligotrophic life-style.

Cyanobacteria

Cyanobacteria and prochlorophytes differ from all other phototrophic bacteria in fundamental ways (Overmann

and Garcia-Pichel, 2006). The oxygenic photosynthesis, conducted by cyanobacteria, requires photosystems acting over a wide redox span. To split the water molecules, the reduction potential of chlorophyll in photosystem II must be more positive than that of the O_2/H_2O couple. Excited electrons are transferred, via several redox carriers, to a second photosystem (PS I), capable of NAD(P)H regeneration. The reducing power is particularly needed for carbon dioxide fixation (for fixation of 1 mol CO_2 , 2 mol NADPH is required), carried out by the Calvin cycle. A unique feature for Cyanobacteria are phycobilins as accessory (light harvesting) pigments, an adaptation to low light conditions. Like plastids, cyanobacteria contain intracytoplasmic thylakoid membranes as additional compartments for the membrane-bound photosystems.

Cyanobacteria are the morphologically most diverse group of bacteria, with some organizational levels analogous to eukaryotic algae (Figure 2c; Waterbury, 2006). Many species are filamentous. They are present in marine and freshwater, as well as in terrestrial habitats (Figure 2c, d). Some live in symbiotic relationship to higher plants (owing to the cyanobacterial nitrogen fixing activity). Several filamentous species carry out nitrogen fixation in specialized cells (heterocysts), lacking the oxygen evolving photosystem II.

Since cyanobacteria are responsible for oxygenation of the early atmosphere, the group has left the possibly deepest impact ever on earth's ecosystems. They are still of global importance for carbon cycling. Marine species are responsible for an estimated 20–40% of carbon dioxide fixation in oceans (e.g., Campbell and Vault, 1993). Since recent Cyanobacteria and the endosymbiotic plastids of green plants have common ancestors, most of the photosynthetic processes are basically due to the activity of Cyanobacteria and their ancestors.

Firmicutes/Actinobacteria

Next related to Cyanobacteria are the Firmicutes/Actinobacteria phyla (Stackebrandt and Schumann, 2006; Madigan et al., 2009). A common feature of all species within these groups is the lack of an outer membrane. Most members of the groups are chemoheterotroph and exhibit a thick peptidoglycan layer, resulting in a positive reaction of the Gram stain. Thus, the organisms are also referred to as “Gram-positive.” The thick cell wall may be also considered as an adaptation to the high osmotic stresses in terrestrial ecosystems (i.e., soil). The genera *Bacillus* and *Clostridium*, but especially the filamentous Actinobacteria (the genus *Streptomyces*, in particular) are important groups in soil habitats. Interestingly, also a small group of photosynthetic genera belongs to the Firmicutes. *Heliobacterium* and related genera are anaerobic, photoheterotrophic soil bacteria, with a minimal photosynthetic apparatus and incapable of carbon dioxide fixation (Asao and Madigan, 2010). *Frankia* genera are important nitrogen-fixing symbionts in alder roots. The production of different antibiotic agents

is another important feature, especially in Actinobacteria and *Bacillus*. Another unique feature within this lineage is the formation of endospores (Figure 2e).

Key genera of endospore formers are *Bacillus* and *Clostridium*. Whereas bacilli are aerobic respiratory organisms, clostridia lack a respiratory chain and are obligate anaerobic, fermenting organisms. They are important for anaerobic degradation of organic compounds, mostly producing organic acids (Table 4). Several clostridia as well as related acetogenic bacteria (e.g., *Acetobacterium*, *Acetogenium*) grow anaerobically either by using carbon dioxide as the terminal electron acceptor in anaerobic respiration with hydrogen as substrate (i.e., chemolithoautotrophically), or by fermenting carbohydrates. In either case, the acetyl-CoA pathway is used to reduce carbon dioxide to acetate. In the course of carbon dioxide reduction to acetate, a sodium ion gradient (instead of a proton gradient) across the membrane is generated that drives ATP synthesis.

Lactic acid bacteria obtain energy solely by fermentative processes. They typically have limited biosynthetic abilities, and need external sources of amino acids, vitamins, purines, and pyrimidines. This life-style is an adaptation to commensalism with other organisms: lactic acid bacteria mainly live on (decaying) plant leaves and fruit, the skin surface and the intestinal mucosa of mammals. Due to their ability to produce high amounts of lactic acid from carbohydrates (including lactose), their habitats are difficult to colonize by competing microorganisms. This also excludes pathogens from mucosal tissue. Another beneficial effect is the conservation of food (especially dairy products) by lactic acid fermentation.

Interestingly, some members of the Gram-positive lineage lost their peptidoglycan layer. These cell wall-less bacteria (key genera *Mycoplasma*, *Spiroplasma*) live as parasites on animal and plant tissue. The lack of a cell wall facilitates the flow of substrates from the host to the bacterium.

Proteobacteria

The most diverse bacterial lineage, the Proteobacteria, is divided into five subdivisions (alpha, beta, gamma, delta, and epsilon). Within most subdivisions, all metabolic key processes, ranging from chemo- and photoautotrophy to chemoheterotrophy, respiration, and fermentation (Tables 1–4), are common (Kersters et al., 2006; Madigan et al., 2009). Here, just the ecologically most important life-styles are pointed out. At least in three subdivisions, photoautotrophs are present (Overmann and Garcia-Pichel, 2006). All of them carry out anoxygenic photosynthesis with one photosystem; different types of intracytoplasmic membranes (lamellar, spheroidal) can be found (Tucker et al., 2010). Electron donors are reduced sulfur compounds (such as H_2S) in purple sulfur bacteria (Figure 2f) and mostly organic compounds (H_2S also in low concentrations) in purple non-sulfur bacteria. Purple non-sulfur bacteria are photoheterotrophic

organisms that utilize external carbon sources, if available. Most of them also fix carbon dioxide by the Calvin cycle.

Chemolithoautotrophy occurs in all proteobacterial subdivisions. Interestingly, ammonia and nitrite oxidation is mainly confined to the Proteobacteria. In four subdivisions (and one additional, recently discovered lineage, related to Proteobacteria) obligate chemolithotrophic nitrifying bacteria, oxidizing either ammonia to nitrite or nitrite to nitrate are present. Like phototrophs, also nitrifying bacteria contain internal membranes. Oxidation of sulfur and iron is represented by several groups in four proteobacterial subdivisions. Sulfur-oxidizing genera have been found in four proteobacterial subdivisions. Some genera are acidiphilic (e.g., *Acidithiobacillus*, *Thiomonas*). Among sulfur oxidizing chemolithotrophs (thiotrophic bacteria), exceptionally large morphotypes were described (*Beggiatoa*, *Thioploca*, *Thiomargarita*). Several sulfur oxidizers, especially from the gamma-subgroup, live in symbiosis with marine mollusks (Dubilier et al., 2008). Oxidation of hydrogen, already mentioned for some bacterial stem lineages, is also widespread in Proteobacteria. All hydrogen oxidizers are facultative chemolithotrophs, that is, they are also able to grow on organic compounds (Kelly and Wood, 2006).

Up to now, the aerobic methanotrophy is mainly confined to Proteobacteria, though recently, a methanotrophic verrucomicrobial bacterium could be found (Chistoserdova et al., 2009). Methylotrophic bacteria oxidize a variety of C₁ compounds (methanol, methylamine, formate). All methanotrophs possess methane monooxygenase as key enzyme for hydroxylation of the chemically inert methane to methanol. Some methanotrophic bacteria are also symbionts in marine animals.

Several genera are well-known model organisms especially for medical microbiology, such as pseudomonads and enterobacteria. Both groups are chemoorganotrophic, respiratory bacteria, enteric bacteria are facultative anaerobes. In global cycles, however, these organisms are largely insignificant. Especially enteric bacteria (within the gamma-subdivision), as commensals and pathogens of diverse higher organisms are well adapted to their hosts.

Sulfate and sulfur reduction is not only restricted to Proteobacteria. *Archaeoglobus*, as an example, is an archaeon, *Thermodesulfobacterium* is a deeply branching genus close to the root of the bacterial phylogenetic tree. Most of the sulfate- and sulfur-reducers are, however, proteobacteria that belong to the delta-subdivision. They are obligate anaerobes using mainly hydrogen, fatty and other organic acids or alcohols as energy sources. Sulfate or elemental sulfur serve as the terminal electron acceptors in an anaerobic respiration with hydrogen sulfide as product. The organic compounds are either oxidized to acetate or to carbon dioxide. These organisms are geochemically important, and are widespread in anaerobic sulfate-rich environments (Barton and Fauque, 2009).

Nitrogen fixation is a feature of multiple bacterial and archaeal genera, only a few groups are important symbiotic organisms. The alpha-proteobacterial Rhizobia

conduct specific symbiosis with legume plants by formation of root nodules.

Several proteobacterial groups exhibit differentiated life cycles: filamentous beta-Proteobacteria like *Spaerotilus* form bundles of sheathed filaments in eutrophic freshwater habitats. Under unfavorable conditions, flagellated swarmer cells are liberated from the open tip of a sheath. Sheaths of *Leptothrix* are involved in the precipitation of Fe³⁺ and oxidation of Mn⁴⁺. In iron-rich waters, mass developments of iron oxide-covered sheaths form large flocculent layers, which are also involved in the formation of bog iron deposits (Crerar et al., 1979). Prosthecae bacteria are primarily found among the alpha-proteobacterial subgroup. Members of this group have many different types of extensions (prosthecae) that contain cytoplasm and are bounded by the cell wall. Similar extensions are formed by the genera *Hyphomicrobium* and *Rhodomicrobium*. Daughter cells arise as growing buds from the hyphal tips. In *Caulobacter*, a stalk attaches the cell to a surface, whereas at the distal cell pole, a flagellated swarmer cell is formed. After division, the swarmer attaches to a new place and will form a new stalk at the formerly flagellated pole (Angert, 2005). The myxobacteria have a complex life cycle, which culminates in the production of fruiting bodies containing resting structures called myxospores. The formation of these structures requires the cooperation and coordinated differentiation of large numbers of cells. Aggregates of cells form through a chemotactic response (Zusman et al., 2007).

Summary

The brief overview points out that bacteria are taxonomically as well as metabolically more diverse than Archaea. Though the phylogenetic relationships among the bacterial phyla is still a matter of debate, several lines of evolutionary developments can be stated.

Chlorophyll-dependent photosynthesis must have been developed early in bacterial evolution, though some lineages may also have acquired genes of the photosynthetic apparatus by horizontal gene transfer. Fixation of carbon dioxide is not conducted via the Calvin cycle in stem groups, but a common feature in Cyanobacteria and Proteobacteria.

Except from Firmicutes/Actinobacteria and Planctomycetes, bacterial cell envelopes consist of two double-layer membranes. It is a matter of debate, if the Firmicutes are a lineage closest to the root of the bacterial phylogenetic tree or if the membrane got lost as a secondary event. The volume enclosed by both membranes, the periplasmic space, is, especially in Proteobacteria, of significance for cellular transport, DNA transfer, and cellular motility. Intracytoplasmic membranes are widespread in Proteobacteria as well as Cyanobacteria, but have not yet been detected in the basal lineages or in Archaea.

Several major phyla contain symbiotic and pathogenic organisms, especially Firmicutes and Proteobacteria

(as far as we know, no Archaeon is pathogenic in a strict sense). Especially within the bacterial “crown group,” complex host–symbiont/pathogen interaction has been developed. Mitochondria have very likely an alpha-proteobacterial ancestor (Gray et al., 1999).

Though biofilms, as an elementary type of multicellular organization, are already found in Archaea, some true multicellular stages in bacteria exhibit elaborate cellular differentiations and complex life cycles. In aquatic habitats, the organisms sometimes switch from planktonic to sessile stages. Several groups of bacteria exhibit diverse adaptations to terrestrial habitats: Firmicutes develop extremely durable and heat-resistant endospores, streptomycetes grow and develop like zygomycete or ascomycete fungal mycelia with branched hyphae and conidia-like exospores. A similar convergence with life cycles to a eukaryote is carried out by myxobacteria. Their life cycle has some striking analogies to cellular slime molds and represents the most complex pattern of bacterial differentiation known so far.

In brief, the development of photosynthesis, the colonization of terrestrial (soil habitats), and the interaction with eukaryotic hosts, are besides the diverse metabolic capabilities, the major achievements of bacteria.

BACTERIOPLANKTON

Thomas Pommier
 CNRS-Université Lyon, Villeurbanne, France

Synonyms

Aquatic bacteria

Definition

Bacterial component of the plankton that drifts in the water column of both seawater and freshwater ecosystems.

Introduction

The name bacterioplankton comes from the association of the Greek word *πλαγκτός* “*planktós*,” meaning “wanderer” or “drifter,” and bacterium, a word coined in the nineteenth century by Christian Gottfried Ehrenberg (Thurman, 1997). In contrast to land, microbes drive the ecology of the aquatic environments both as producers and consumers of fixed carbon. Their colossal biomass vastly outreaches the ones of all other members of the oceanic and freshwaters biota. Considering its size, the Ocean encompasses more bacteria than the count of known stars (estimated to 10^{21}) in the Universe. Though its role in aquatic ecosystems was for long eluded, the bacterioplankton carries out the largest fraction of the biological activity and occupies a range of ecological niches.

Enumeration and description

Since the beginning of microbiology, counting the number of bacteria that occur in various aquatic environments has been an exciting subject of investigation. Because of the size and the mobility of the bacterioplankton, early bacteriologists had difficulties to simply enumerate them with a conventional microscope. With the development of appropriate techniques (e.g., size selection on membrane filters and DNA/RNA specific fluorochromes stainings), as well as advances in microscopy, bacterioplanktonic cells could be observed and counted (Hobbie et al., 1977). This method indicated that the bacterioplankton were on an average $\sim 10^6$ cells per milliliter of water. Recent developments in flow cytometry have confirmed and sharpened these counts (Amann et al., 1990). In the water column, the bacterioplankton is also exposed to grazing activity by larger protists and viral infections, but irrespective to variations in primary productivity, these two causes of mortality seem to maintain a relatively constant abundance.

Though it is not always mentioned in the current literature, a clear distinction should be made between the fraction of the bacterioplankton that is attached to drifting particles of organic matters (also called “marine snow” in the marine environment) and the fraction that is free-living in the water column. A common trait for free-living bacterioplankton is their small size, or small cell volume, ranging from 0.1 to $0.22 \mu\text{m}^3$, which is about ten times lower than that of the most attached bacterioplankton in aquatic habitats or in soils (Fenchel et al., 1998) and the most cultured cells.

Bacterioplankton biological activity

Based on both direct observations and indirect measurements of bacterial growth rates in whole seawater (e.g., frequency of dividing cells (Hagström et al., 1979), radioactive thymidine or leucine incorporation (Fuhrman and Azam, 1982; Chin-Leo and Kirchman, 1988)) as well as when bacterial grazers (protozoans) were removed (Vacelet, 1972), generation times (i.e., the time required to double population) of most bacterioplanktons range from 0.049 to 0.080 h^{-1} .

Because a significant proportion of the bacterioplankton (99%) of the total counted cells fail to grow on nutrient-rich agar plates, it has been suggested that most counted cells were either starving cells, dormant (Stevenson and Schmidt, 1998) or even non-viable cells (Kjelleberg et al., 1987). Different in situ measurements of amino acids or glucose uptake by microautoradiography (Hoppe, 1976) indicate that from 5% to >60% of the cells are metabolically active in different aquatic environments (Tabor and Neihof, 1984; Fuhrman and Ferguson, 1986; Smith and del Giorgio, 2003). Whether or not most bacteria in aquatic environment are dormant remains controversial, most scientists will agree however that the bacterial community, as a whole and over

long period of time, plays a paramount role in global biochemical processes.

The blue-green algae, or *Cyanobacteria*, are the “plants” of the bacterioplankton and carry out photosynthesis, which supports the entire ocean food web. In the open ocean, these phototrophic bacteria are responsible for about 80% of the total oceanic primary production, which represents about half of the planet’s primary production (ranging from 35 to 65 Gt of carbon per year) (del Giorgio and Duarte, 2002). Moreover, a new type of phototrophy has recently been discovered among marine bacterioplankton that carry bacteriorhodopsin molecules, which scavenge light to create an energetic gradient of protons (Beja et al., 2001). Since ~13% of the bacterioplankton cells in the photic zone may carry out proteorhodopsin-based phototrophy (Sabeji et al., 2005), this metabolism surely has a global significance and may be the foremost future investigation field in aquatic microbiology.

However in numbers, marine bacterioplankton are considered mostly heterotrophs, or more precisely saprotrophs, and obtain energy by consuming dissolved organic matter (DOM) released by larger aquatic animals (Smith et al., 1992) or by phytoplankton exudation (Larsson and Hagström, 1979). This activity, known as the “microbial loop” (Azam et al., 1983), is crucial to the aquatic trophic foodwebs because essential inorganic nutrients are recycled through bacterial metabolism into the water column.

Heterotrophic and phototrophic bacterioplankton are continuously grazed by protozoans (i.e., mostly flagellates and ciliates), which are later consumed by larger zooplankton, which are subsequently consumed by fishes. Phages (i.e., viruses infecting bacteria) also affect DOM turnover by lysing cells, which releases organic matter available to surrounding bacterioplankton cells (Proctor and Fuhrman, 1990).

A large fraction of the carbon flow in the aquatic ecosystem is processed by heterotrophic bacterioplankton that respire particulate and dissolved organic carbon (DOC) (del Giorgio and Duarte, 2002). Especially with the rapid increase in global atmospheric CO₂ due to modern human activities, this bacterial process is recognized as a key component in global climate regulation (Falkowski et al., 2000).

Bacterioplankton diversity and global distribution

While growth on agar plates, microscopic observations were intensively used to delineate several types of bacteria, their capacity of differentiation showed quickly to be too restrictive and new methods were required to distinguish between two species with similar cell and colony morphologies. Moreover, a general concern grew among microbiologists when they realized that many bacteria counted under the microscope could not be cultivated on agar plate or in liquid media. For instance, marine microbiologists estimated that only 1% of the cells counted

under the microscope formed colonies on agar plates, and named this issue the “Great plate count anomaly” (Jannasch and Jones, 1959; Kogure et al., 1979).

In the early 1980s, a breakthrough in bacterial taxonomy was achieved by Woese et al., who utilized ribosomal ribonucleic acids (rRNA) to catalogue related bacterial species (Fox et al., 1980; Woese et al., 1985, 1987). Applying this approach to aquatic environmental samples often recovers members from about 18 bacterial clades, mostly represented within the α -*Proteobacteria* and γ -*Proteobacteria* phyla. Moreover, members from the *Cyanobacteria*, *Actinobacteria*, *Bacteroidetes*, *Planctobacteria*, *Fibrobacter*, *Chloroflexi* and β -*Proteobacteria* are often retrieved from environmental rRNA genes clone libraries. Interestingly, though some members of the global bacterioplankton community (e.g., the so-called SAR11 clade) are recurrently found in environmental samples, and therefore show a ubiquitous distribution, endemism of rRNA genes is the most common trait of the bacterioplankton, and their diversity follows a latitudinal gradient as observed in the other macro-organisms (Pommier et al., 2007).

The extensive use of the SSU rRNA as phylogenetic marker has actually reached the level where variations in the bacterioplankton composition can be linked to observed changes both in natural (Acinas et al., 1999; Cottrell and Kirchman, 2000; Hollibaugh et al., 2002) and reconstructed environments (i.e., meso- or microcosms) (Riemann et al., 2000). The current view of marine bacterioplankton phylogeny is however being questioned together with the relevance of the SSU rRNA gene to delineate bacterial species.

Conclusions

Though it was for long considered a mass of dormant cells, bacterioplankton has proven to be a key actor in aquatic ecosystems throughout the world. As for many ecosystems, the bacterioplankton drives the whole biological activity of the water foodweb and occupies a huge variety of niches throughout the water column. Further research aims to show the importance of local bacterioplanktonic processes involved in global biogeochemistry.

Summary

The bacterial component of the plankton that drifts in the water column of all aquatic ecosystems is named *Bacterioplankton*. Though it was for long considered solely dormant, this part of the biota is now recognized as a determinant actor on the global recycling of nutrients and at the basis of all aquatic foodwebs. With a million cells per millimeter of water, they represent the most successful organisms, as well as the most diverse biome on our planet. Modern approaches combining molecular biology to epi-fluorescence microscopy have sharpened our knowledge on the abundances, the diversity and the ecology of the bacterioplankton.

BIFs

Definition

Sedimentary deposits of alternating iron-rich (~20–40% Fe) and iron-poor, siliceous (~40–50% SiO₂) mineral layers that primarily precipitated throughout much of the late Archean (2.7–2.5 Ga) and Paleoproterozoic (2.5–1.8 Ga), but then remerged in the Neoproterozoic (~0.8 Ga).

BIF characterization, mineralogy, and distribution

BIFs are globally distributed, with some of the larger formations being those of the Hamersley range in Australia and the Transvaal Supergroup in South Africa (Figures 1 and 2). Other major BIFs include Krivoy Rog Supergroup, Ukraine (2.2 Ga); Labrador Trough, Canada; Lake Superior Region, USA; Gunflint and Biwabik, North America

(2.2–2.0 Ga), Carajás Formation (2.6 Ga) and Urucum Region, Brazil (0.8 Ga).

The mineralogy of the least metamorphosed BIFs consists of chert, magnetite, hematite, carbonates (siderite and dolomite–ankerite), greenalite, stilpnomelane, and riebeckite (Klein, 2005): the presence of both ferric and ferrous minerals gives BIF an average oxidation state of Fe^{2.4+} (Klein and Beukes, 1992). It is generally agreed that none of the minerals in BIF are primary, but that instead, the minerals reflect both diagenetic and metamorphic overprinting. For instance, the primary iron minerals were most likely ferric hydroxide (Fe(OH)₃), greenalite ((Fe)₃Si₂O₅(OH)₄), and siderite (FeCO₃) (Klein, 2005).

Based on their depositional environment, BIFs have been categorized as Algoma or Superior type. Algoma type BIFs are generally small in lateral extent and display a volcanic association (Gross, 1965, 1980; Huston and Logan, 2004), while Superior type BIFs are found in shelf environments, are vast, and are without a dominant volcanic influence. The “Superior” type BIFs, including those in the Hamersley Group, Western Australia and the Transvaal Supergroup, South Africa, are hundreds of meters thick, over 10⁵ km² in areal extent, and contain >10¹³ t of iron (Trendall, 2002). They are characteristically laminated, with alternating Fe-rich and Si-rich layers (Figures 2 and 3). Banding can be observed on a wide range of scales, from coarse macrobands (meters in thickness) to mesobands (centimeter-thick units) to millimeter and sub-millimeter layers (Trendall and Blockely, 1970). Among the latter is the wide variety of varve-like repetitive laminae, known as microbands.

BIFs have also been categorized according to their Fe oxide composition, as hematite or magnetite BIFs (Figure 3) (James, 1954). The former refers to BIFs facies consisting principally or entirely of interbedded chert and (primary) hematite, which are in some places oolitic (e.g., the Gunflint range). The latter describes Fe oxide layers of magnetite that may grade imperceptibly into silicate rock in some areas, be mixed with carbonate, or sprinkled with hematite or chert lenses (James, 1954).

A third categorization of BIF is based on the granular versus nongranular nature of the silica layers. Granules, seen in the 2.0 Gyr Gunflint BIF are approximately 0.5 mm in diameter, irregular, and can be within a chert matrix. They can have a greenalite or magnetite core. These granules, however, do not show the concentric layering seen in hematitic oolites. Non-granular BIFs are typically thin-bedded or laminated and may chiefly be composed of minnesotaite with magnetite and carbonate in some layers (James, 1954).

Banded iron formations and the study of the early Earth

The height of BIF deposition was 2.7–2.4 Ga (Trendall, 2002; Klein, 2005), a timeframe which overlaps with the currently estimated age for the rise of oxygen on the Earth ~2.5 Ga (Anbar et al., 2007). As it is agreed that the

source of iron for these deposits was Fe(II), the Fe(III) minerals in BIF indicate that an oxidizing mechanism was present. Once oxygen began its rise due to the advent of cyanobacteria, it is plausible that an oxic mechanism formed BIF, perhaps even in pockets or oxygen oases. In the case of BIF dated prior to 2.7 Ga, however, an anoxic oxidizing mechanism is required to explain the formation of these vast deposits. The latest BIFs (0.8 Ga), which seem to represent a revival later in the geologic record, may be archives of major climate changes related to the Snowball Earth (Kirschvink, 1992; Kopp et al., 2005). Due to the intricacies of the depositional mechanisms, BIFs have been studied for decades regarding their potential as archives of the early Earth environment, but may also prove to be a detailed record of the early Earth biosphere.

BIF deposition

Depositional setting

Early studies of BIF mineral association (James, 1954), as well as comparative BIFs studies (Trendall, 1968; Beukes, 1973; Gole and Klein, 1981; Simonson, 1985; to name a few) postulated that these sedimentary deposits likely formed on the margins of cratons in semi-restricted, marine basins with minimal wave action (for a comprehensive review, Klein, 2005). They also laid a foundation for both theoretical and experimental geochemical modeling based on atmospheric (oxygen and carbon dioxide) and oceanic (iron and silica) concentrations, which are largely linked to mineralogical, petrologic, and isotopic analyses and have been invoked to describe the BIF deposition mechanism (Drever, 1974; Cairns-Smith, 1978; Han, 1978; Braterman et al., 1983; Baur et al., 1985; Francois, 1986; Garrels, 1987; Morris, 1993).

There is ample evidence that the dominant source of Fe (II) into the Archean ocean was hydrothermal (e.g., Jacobsen and Pimentel-Klose, 1988; Bau and Möller,

1993), but it has also recently been suggested that a significant fraction of the Fe in Archean seawater came from the continents (Alexander et al., 2008). The proximity of the Fe(II) source to the site of deposition, however, is still unclear. The estimated Fe(II) concentration for these basins ranges from 0.02 to 0.5 mM (Holland, 1973; Morris, 1993). This Fe(II) may have been delivered from the deep ocean to the outer continental shelf by upwelling currents from a mid-ocean ridge system (e.g., Holland, 1973). Accordingly, BIFs would sediment from below the wave base (free of wave- and storm-induced currents) onto partially submerged platforms of the continental shelves. Alternatively, Fe(II) could have been directly supplied from plumes in a seamount type system (Isley, 1995), which would curtail the difficulties introduced by the high upwelling rates required in the continental shelf model. After deposition, these sediments would undergo diagenesis, with some BIF sediment possibly even being redistributed to deeper waters via turbidity currents (Krapež et al., 2003).

There is significant evidence that Archean oceans also contained elevated concentrations of dissolved silica, possibly even to saturation with respect to amorphous silica (~2.20 mM; Siever, 1992; Maliva et al., 2005). Under such silica-rich conditions, the direct precipitation of amorphous silica could have taken place directly from the water column onto the sea basin floor (Krapež et al., 2003). Moreover, silica could have reacted with dissolved Fe(II) and precipitated as ferrous or ferric-silicates (Konhauser et al., 2007).

Theories of Precambrian BIF deposition

BIF mineralogy dictates that some form of Fe(II) oxidation was necessary for their formation, yet which mechanism(s) dominated is still highly uncertain (Figure 4). While dissolved Fe(II) readily oxidizes in the presence of oxygen at circumneutral pH, to the rise of oxygen on Earth occurred approximately 2.5 Ga (Kopp et al., 2005; Anbar et al., 2007). An alternative, O₂-independent

Banded Iron Formations, Figure 4 Models of banded iron formation deposition: The traditional model of BIF deposition involves the production of oxygen by cyanobacteria, which is released into the water column to chemically react with hydrothermal dissolved Fe(II) (a). The two proposed mechanisms of deposition in an anoxic ocean water column are the abiotic Fe(II) photooxidation by UV light, which has recently been discounted (Konhauser et al., 2007) (b), and direct microbial Fe(II) oxidation via anoxygenic Fe(II)-oxidizing phototrophy (c).

mechanism is therefore necessary to explain the deposition of the earliest BIF.

Both abiotic and biotic mechanisms of BIF deposition have been put forth. The potential role of microorganisms in BIF was first proposed 4 decades ago (Cloud, 1968) and in part addressed the difficulties in explaining these deposits based on geochemical processes alone (Brown et al., 1995). Yet, BIFs contain very little or no organic carbon (0.5% [w/w], Beukes and Klein, 1992) which makes it difficult to constrain the responsible microbial process

simply based on geochemical and petrographic studies. Any fossil information about the presence of life in the Archean has therefore been garnered from contemporaneous formations. For this reason, isotopic, biomarker, and ecophysiological studies with modern analogues have been implemented in order to supplement the geochemical BIF data and test the plausibility of the depositional models and the role of microorganisms.

Oxygenic photosynthesis model

The traditional model of BIF deposition was first postulated by Cloud (1968). Herein, Fe(II) is abiotically oxidized by photosynthetically produced O_2 , allowing for the indirect biogenic precipitation of ferric hydroxide as shown in Equation 1 (Figure 4a). Under an anoxic atmosphere, this O_2 could have been confined to local "oxygen oases" associated with cyanobacterial blooms in coastal settings (Cloud, 1965, 1973). Cloud (1965, 1973) further proposed that such primitive O_2 -producing photosynthetic bacteria, which lacked suitably advanced oxygen-mediating enzymes, required ferrous iron to detoxify oxygen. If so, these microorganisms would have flourished specifically when Fe(II) and nutrients were made episodically available. Once oxygen was present, aerobic Fe(II) oxidizers could also have contributed to biogenic Fe minerals precipitation (Holm, 1989).

The oldest evidence to support the presence of cyanobacteria during the time of BIF deposition came from the 3.45 billion-year-old Apex cherts, Warrawoona, Australia (Schopf, 1993). These findings, however, have since been challenged by Brasier et al. (2002) as being secondary artefacts formed by Fischer–Tropsch type reactions associated with seafloor hydrothermal systems. In fact, Buick (1988) maintained that the chert matrix of the "oldest microfossils" is a secondary hydrothermal deposit of younger age that cross-cuts the primary bedding. The use of kerogen as a marker of past life in these formations has also been challenged by experiments demonstrating the abiotic pathways of kerogen synthesis; simple organic hydrocarbons of abiological origins (e.g., formaldehyde) readily condense onto silica–carbonate inorganic filaments, and subsequently polymerize under gentle heating to yield kerogenous products (García-Ruiz et al., 2003).

In light of these studies, stronger evidence for the presence of cyanobacteria comes from the stromatolitic assemblages of the 2.7 Gyr Tumbiana Formation, Western Australia. The presence of oxygenic photosynthesis in these formations is based on their likely habitat in sulfate-deficient evaporative lakes (Buick, 1992). This is further supported by the earliest undisputed fossil assemblages of the 2.6 Gyr Campbell Group, South Africa, that include cyanobacterial genera which helped form stromatolitic reefs in shallow subtidal to intertidal settings (Altermann and Schopf, 1995).

Biomarkers, organic compounds derived from more complex precursors which still resemble the original biological molecule after a long burial history, may be used to identify a specific group of organisms in ancient rock. For example, 2 α -methylhopanes are derivatives of prominent lipids in cyanobacteria (methylbacteriohopanepolyols). Abundant amounts were extracted from bitumens of the 2.6 Gyr Marra Mamba Iron Formation and the 2.5 Gyr Mt. McRae Shale of the Hamersley Group, Western Australia (Brocks et al., 1999; Summons et al., 1999). As these compounds were first solely found in cyanobacteria, their presence was first interpreted as diagnostic of oxygenic photosynthesis, however, they have recently been detected in anoxygenic phototrophs (Rashby et al., 2007), which weakens the use of this biomarker as conclusive proof of oxygenic photosynthesis in ancient rock.

Specific steranes are more indicative of this metabolism. These are 28- to 30-carbon isomers and are unique alteration products of sterols known from extant eukaryotic cell membranes. The only prokaryotes known to synthesize sterols have biosynthetic pathways leading to different structural isomers. Importantly, O₂ is required for the biosynthesis of sterols, hence, their extraction from Archean rock suggests that at least some dissolved oxygen (~ 0.002 ml O₂ L⁻¹) was present at the time of their production (Runnegar, 1991). To date, there is no experimental evidence to support the alternative theory that steranes may have been produced via an anaerobic pathway utilizing hydrogen peroxide or organic peroxides (Fischer and Pearson, 2007), which make them a specific biomarker of oxygenic photosynthesis. They are found, for example, in the 2.7 billion-years-old shales of the Jeerinah Formation, Hamersley Group (Brocks et al., 1999). Their presence in these shales is particularly intriguing as other redox-sensitive proxies suggest that oxygen arose much later in earth history (Rye and Holland, 1998; Rasmussen and Buick, 1999; Farquhar et al., 2000). Only the presence of localized oxygen oases can explain these conflicting results.

UV photooxidation model

Prior to the rise of atmospheric oxygen and the development of a protective ozone layer, the Earth's surface was also subjected to high levels of ultraviolet radiation. This led to a theory of BIF deposition in which UV radiation drives an abiotic mechanism of Fe²⁺ oxidation and Fe(III) mineral precipitation. Specifically, under conditions of anoxia and high dissolved Fe(II) concentrations, dissolved ferrous iron species, such as Fe²⁺ or Fe(OH)⁺, can absorb radiation in the 200–400 nm range. Dissolved ferric iron is formed (Equation 2), which hydrolyzes to form ferric hydroxide at circumneutral pH (Cairns-Smith, 1978; Braterman et al., 1983) (Figure 4b).

These experiments, however, were recently carried out in complex solution simulating disequilibrium Precambrian ocean water chemistry in which Fe(II)-rich hydrothermal waters react with ambient Si-saturated seawater also containing high HCO₃⁻ concentrations (Konhauser et al., 2007). It was shown that the oxidation effects of either UVA or UVC were negligible in fluids with high dissolved Fe(II), Si, and HCO₃⁻, compared to the precipitation of ferrous-iron-silicates and ferrous carbonate. This suggests that under such conditions Fe²⁺ would have been largely deposited as Fe(II) minerals instead of being oxidized by UV radiation. The fact that Fe(III) minerals are present in BIF therefore suggests that in the absence of O₂ the alternative anoxic depositional mechanism, Fe(II) oxidation by anoxygenic phototrophs, drove Fe oxide deposition.

Anoxygenic Fe(II)-oxidizing phototroph model

Anoxygenic photosynthesis was first suggested as a BIF deposition mechanism by Garrels et al. (1973) and Hartman (1984). They proposed that light, not O₂, may have coupled the carbon and iron cycles via photosynthesis that used Fe(II) rather than H₂O as an electron donor and produced Fe(III) rather than O₂ (Figure 2c). It was only 2 decades later that the plausibility of this theory was validated by the discovery of a modern Fe(II)-oxidizing phototroph (Widdel et al., 1993). Seven extant strains of anoxygenic Fe(II)-oxidizing phototrophs are now known to use light energy to catalyze the oxidation of Fe(II) and the corresponding reduction of CO₂, which yields biomass and ferric hydroxide as shown in Equation 3.

In the context of BIFs, anoxygenic Fe(II)-oxidizing photosynthesis (photoferrotrophy) is the only direct biological process that can precipitate Fe(III) minerals in the absence of oxygen.

While no direct evidence exists for the presence of these strains on the Archean Earth, various lines of evidence support the plausibility of anoxygenic phototrophs in BIF deposition. Ecophysiological studies performed with modern anoxygenic Fe(II)-oxidizing phototrophs test the plausibility of this deposition mechanism. It was shown that these strains inhabit a wide range of growth environments; being globally distributed and present in fresh and marine waters (Ehrenreich and Widdel, 1994; Heising et al., 1999; Straub et al., 1999; Croal et al., 2004; Jiao et al., 2005). These organisms do not have a unique form, all being rod-shaped (Figure 5), yet morphological variety is apparent, one example being the presence of vacuoles in one strain, *Thiodictyon* sp. strain F4 (Croal et al., 2004). These strains also utilize a variety of substrates, such as acetate, FeS and H₂, which suggests that they are versatile enough to be an integral group in both

Banded Iron Formations, Figure 5 Anoxic Fe(II)-oxidizing phototrophs "*Rhodobacter ferrooxidans*" sp. strain SW2 (a, b) and *Chlorobium ferrooxidans* sp. strain KoFox (c) form aggregates with the Fe(III) hydroxides produced by their metabolism. Many cells are not encrusted by, but only associated with, the Fe(III) minerals that may have been the primary minerals in BIFs.

ancient and modern environments. Modeling of the photo-synthetic Fe(II) oxidation rates determined in these studies suggest that such microorganisms could have accounted for all of the Fe(III) initially deposited in primary BIF sediment (Kappler et al., 2005). Importantly, while the Fe(II) oxidation rate of these strains is dependent on light intensity, anoxygenic phototrophs can oxidize Fe(II) in light regimes befitting the photic zone of ocean water (of a few hundred meters depth) (Kappler et al., 2005). Also, Fe(II) oxidation is not hindered by high concentrations of dissolved silica (tested at 2 mM Archean ocean concentration) (Siever, 1992; Konhauser et al., 2007).

While modern studies show that cyanobacteria are indeed important in stromatolite building through the trapping and binding of carbonate grains in their filaments and extracellular polymers, several anaerobic pathways, such as sulfate reduction (e.g., Visscher et al., 1998; Paerl et al., 2001), are also integral in carbonate cementation and localized alkalinity generation. Indeed, sequence analysis of small subunit rRNA genes amplified with PCR from genomic DNA showed that anoxygenic phototrophs represent a considerable fraction of biomass in the modern stromatolite communities of Hamelin Pool, Shark Bay, Australia (Papineau et al., 2005). Recently, Bosak et al. (2007) experimentally demonstrated that the anoxygenic phototroph, *Rhodospseudomonas palustris*, stimulates the precipitation of calcite in saturated solutions and builds stromatolite-like structures.

While 2 α -methylhopanes were first considered diagnostic of oxygenic photosynthesis, they may have a structural function and are not related to cell metabolism. Indeed, several facultative and obligate anaerobes possess the genes for hopanoid biosynthesis, and *Geobacter sulfurreducens* produces a wide variety of complex hopanoids structurally related to 2 α -methylhopane under strictly anoxic conditions in pure culture (Härtner et al., 2005; Fischer and Pearson, 2007). Moreover, it was recently demonstrated that an anoxygenic Fe(II)-oxidizing phototroph, *Rhodospseudomonas palustris*, generates substantial quantities of 2-methylhopanoids in the absence of oxygen (Rashby et al., 2007), which renders their presence in ancient rocks alone as an unsatisfactory marker for a specific metabolism.

Pigment biomarkers may offer further evidence of a microbial role in BIF. Okenane, the fossil hydrocarbon biomarker of the carotenoid pigment precursor, okenone, was recently found in the 1.64 billion-year-old Barney Creek Formation in northern Australia, a marine, sub-wavebase base succession. This pigment is exclusively found in purple sulfur bacteria and in recent sediments under euxinic conditions (Brocks, 2005).

Isotopic evidence and the BIF depositional mechanism

The Fe isotope composition of iron minerals in BIFs is markedly different from the homogenous values seen in

igneous rocks and many modern marine sediments ($\delta^{56}\text{Fe}$ $0.00 \pm 0.05\text{‰}$). Specifically, the hematite, magnetite, Fe-carbonate, and pyrite Fe isotope compositions reflect the various processes contributing to BIF formation; equilibrium fractionation of minerals, a variation in the fluid isotope composition from which the minerals precipitated, as well as microbial processes (Johnson et al., 2003; Johnson and Beard, 2005).

In an effort to elucidate the role of microorganisms in the formation of BIF, the Fe isotope fractionation carried out by Fe metabolizing microorganisms was analyzed in controlled laboratory studies of both pure and enrichment cultures. These show that ferric hydroxides are enriched in the heavy isotope relative to Fe(II) for anoxygenic Fe(II)-oxidizing phototrophy ($1.5 \pm 0.2\text{‰}$) (Croal et al., 2004), microbially catalyzed aerobic Fe(II) oxidation at low pH (Balci et al., 2006), aerobic chemical oxidation (Bullen et al., 2001), and UV Fe(II) oxidation (Straton et al., 2006), suggesting that all major processes produce similar Fe isotope fractionations.

The isotopic fractionations reported from laboratory experiments correlate well in part with the values recovered from Archean to early Proterozoic banded rocks of the Transvaal Supergroup, South Africa. $^{56}\text{Fe}/^{54}\text{Fe}$ values in hematite are as high as $+0.75$ to $+1.0\text{‰}$ (Johnson et al., 2003) when compared to the Fe from hydrothermal vents ($\pm 0\text{‰}$). As UV photooxidation was recently ruled out as a significant BIF deposition mechanism (Konhauser et al., 2007), these positive to near-zero $\delta^{56}\text{Fe}$ values are even consistent with (although not proof of) phototrophic Fe(II) oxidation in the early Archean oceans. However, the similarity in values from anoxygenic phototrophs with those of Fe(III) oxides formed by chemical oxidation and microbially catalyzed aerobic Fe(II) oxidation make it difficult to distinguish the key biotic and abiotic processes (Bullen et al., 2001; Balci et al., 2006). Iron isotope fractionation during oxidation itself is obviously independent of the oxidation mechanism (chemical or biological) because of the very rapid isotopic exchange between aqueous Fe^{2+} and Fe^{3+} , allowing isotopic equilibrium to be attained between reduced and oxidized aqueous species. Moreover, in these ancient formations interpretation of the isotopic signature is complicated by the complexity of the depositional environments, the diagenetic processes which have altered the Fe mineralogy, including the infiltration of external fluids during diagenesis and/or low temperature metamorphism which may have erased the primary isotope record (Hoefs, 1997; Johnson et al., 2003). Indeed, the large variation of $\delta^{56}\text{Fe}$ (-2.5 to $+1.0\text{‰}$ relative to the bulk Earth) in late Archean and early Paleoproterozoic BIFs from the Transvaal Supergroup, South Africa incorporates the entire range of values measured on the Earth.

The carbon isotopic record of BIFs is constrained by the low occurrence of organic carbon (0.5% [w/w], Beukes and Klein, 1992) in these structures. Carbon isotope signatures observed in contemporaneous formations may offer information about organisms which were present at the

time of deposition, but whose record was erased, for example, by postdeposition diagenetic processes. In such ancient formations, negative carbon isotope signatures are often interpreted as an indicator of life. Organisms transform inorganic carbon (e.g., CO_2 or HCO_3^-) via autotrophic pathways into organic carbon, preferentially incorporating the lighter isotope, ^{12}C , into the organic phase and producing residual CO_2 enriched in the heavier isotope, ^{13}C . Cyanobacteria, for example, display a $\delta^{13}\text{C}$ range of -4 to -35‰ (Schidlowski, 2000). For example, early photosynthesis has been linked to mat-forming communities in microfossiliferous units within Archean formations from Western Australia and South Africa (e.g., Altermann and Kazmierczak, 2003; Tice and Lowe, 2004) by carbon isotopic values ranging from -20‰ to -35‰ , as well as the $-31.0\text{‰} \pm 4.7$ values from organic carbon in early Proterozoic cherts (Strauss et al., 1992).

Key to this approach is the consideration of overlapping degrees of fractionation produced by various carbon fixation pathways (reductive acetyl-CoA, reductive citric acid, Calvin cycle, and hydroxypropionate). This makes it impossible to determine whether these putative biological residues were remnants of chemolithoautotrophs, evidence for early photosynthesis, or abiological C-isotopic fractionations, such as those associated with Fischer-Tropsch type processes ($\Delta^{13}\text{C}$ between -50‰ and -100‰).

Theories of iron and silica mineral layering

One of the characteristic features of BIF are the alternating Fe-rich (hematite, magnetite, and siderite) and the silicate/carbonate (chert, jasper, dolomite, and ankerite) layers that form bands varying in thickness from the microscale (μm in thickness) to meter-thick units (Trendall, 1968; Klein and Beukes, 1992; Klein, 2005). Some deposits, such as in the Dales Gorge Member, Hamersley Group, Western Australia, show laterally contiguous layers up to a 100 km in distance. This suggests that some unifying trigger of iron and silicate mineral precipitation exists over large areas with some regularity, most likely one which largely subdues the precipitation of one mineral while stimulating that of the other. Furthermore, given the range of band thickness from the micro- to macro-scale, as well as the complex mineralogy, it is most likely that layering in BIF is determined by a multilayered mechanism; one producing primary layering and a second mechanism acting post deposition via diagenesis.

Following this observation, many models attribute the primary genesis of micro and mesobands to seasonal stratification, or to yearly or decadal climatic cycles. Episodic hydrothermal pulsation and upwelling of Fe(II)-rich waters into depositional basins already saturated with dissolved silica have been invoked to explain these bands; silicification is driven by seasonal evaporation of basin waters (Holland, 1973; Garrels, 1987; Jacobsen and Pimentel-Klose, 1988; Siever, 1992). This mechanism, however, does not explain the laterally contiguous fine-scale banding, nor does it resolve why the iron and silica

do not co-precipitate but rather form distinct mesobands (Trendall, 1968; Garrels, 1987; Morris, 1993). Furthermore, in light of increasing evidence for an active microbial component in the Fe cycle (Johnson et al., 2003), the potential importance of microorganisms in BIF deposition models has been suggested. Indeed, a mechanism of alternating Fe and silicate mineral layer deposition with a microbial driver triggered by temperature has been recently presented (Posth et al., 2008).

Diagenesis in BIFs: oxidation and the reduction of Fe(III) minerals

The average oxidation state of $\text{Fe}^{2.4+}$ can be described by the simultaneous deposition of Fe(II) and Fe(III). Yet, this mixed oxidation state can also be explained by partial biotic or abiotic diagenetic re-reduction of precipitated Fe(III) to Fe(II). Experimental studies testing such diagenetic mineral transformations in the presence and in the absence of biomass have not yet been reported. Nonetheless, the presence of magnetite as (1) disseminated grains within but obscuring sedimentary laminae, (2) laminated beds that clearly truncate sedimentary layering, (3) layer-discordant veins, and (4) cleavage fills, suggests such a secondary origin (Ewers and Morris, 1981; Krapež et al., 2003).

The diagenetic or microbial modification of Fe(III) after sedimentation to produce siderite (FeCO_3) and magnetite (Fe_3O_4) requires a reductant. Even if a surface water oxic zone was generated by cyanobacterial activity (Summons et al., 1999), deep waters remained anoxic (e.g., Canfield, 1998). The dominant anaerobic respiratory processes would have oxidized fermentation products in the bottom waters and/or shallow sediments (Rothman et al., 2003). The scarcity of O_2 limited both nitrate and sulfate. This is supported by both negligible sulfur isotopic fractionations between late Archean and early Paleoproterozoic sulfide and sulfate minerals (Strauss, 2003), as well as the absence of pyrite in BIF, except in association with interlayered shaley units (Ewers and Morris, 1981). The significance of manganese pathways is also refuted by the low relative concentrations of Mn(II) released in hydrothermal effluent, as well as the lack of phototrophic or nitrate-independent Mn(II) oxidizing bacteria in modern environments. In contrast, abundant ferric hydroxide deposited as BIF may point to the importance of a microbial process which coupled the oxidation of organic carbon, dead planktonic bacteria, to the reduction of ferric iron producing such reduced iron mineral phases.

Evidence of BIF diagenesis via ancient microbial Fe(III) reduction comes from Fe isotopic ratios in Fe-bearing minerals from Archean sedimentary rocks that closely mimic those observed during modern dissimilatory Fe(III) reduction. For instance, analyses of carbon- and magnetite-rich rocks, from the 2.9 Gyr Rietkuil Formation, Witwatersrand Supergroup, South Africa, revealed $\delta^{56}\text{Fe}$ values as low as -2.3‰ (Yamaguchi et al., 2005). These negative fractionations are very similar to what might be expected from multiple stages of Fe(III)

reduction (Johnson et al., 2004), where each single-step bacterial Fe(III) reduction leads to isotopically light ($\delta^{56}\text{Fe} < 1.2\text{‰}$) aqueous Fe(II) relative to the initial ferric hydroxide substrate (Icopini et al., 2004). The importance of Fe(III) reduction as a means to explain the iron fractionations has, however, been challenged by Rouxel et al. (2005). They suggested that highly variable, but negative values in pyrite from black shales (0.5‰ to -3.5‰) between 2.8 and 2.3 Ga more likely reflect the initial deposition of Fe oxides (e.g., BIFs) which preferentially removed isotopically heavy ^{56}Fe , driving the ocean waters to the negative $\delta^{56}\text{Fe}$ values recorded in pyrite. This interpretation is consistent with the notion that partial biological and abiological processes oxidized the dissolved Fe(II) brought into the shallow waters, but is problematic in light of recent studies showing significant isotopic variations for minerals within close proximity and thus, time of deposition (Johnson et al., 2008). This variation is perhaps most easily explained if the Fe isotopes reflect diagenetic pathways and not the bulk seawater (Johnson et al., 2008).

BIF diagenesis and the Archean marine Fe cycle

BIFs have recently been studied to develop a model of the Archean marine Fe cycle. In doing so, Konhauser et al. (2005) made two assumptions. First, they assumed that the bulk of the Fe(II) component in Fe-rich BIF-type macrobands formed diagenetically through biological Fe(III) reduction, i.e., the magnetite is not primary. Based on a predicted rate of Fe(III) deposition annually (1 mm year^{-1}), they then quantified the electrons that were needed to generate the amount of magnetite as reported in BIF (one third of Fe minerals; Morris, 1993). Second, they quantified the amount of photosynthetic Fe(II)-oxidizer biomass that may have been generated in the photic zone of the water column (based on Kappler et al., 2005), in order to estimate the amount of Fe recycled prior to burial. The results demonstrated that under ideal growth conditions, as much as 70% of the biologically formed Fe(III) could have been recycled back into the water column via fermentation and organic carbon oxidation coupled to microbial Fe(III) reduction. It was also suggested that some of the biomass may have been ultimately consumed via methanogenesis, i.e., coupling the oxidation of acetate or H_2 to methane formation. The hypothesis is to some extent corroborated with the analyses of kerogens (extracted from rocks 2.8 and 2.6 Gyr) with highly negative $\delta^{13}\text{C}$ signatures (between -40‰ and -60‰) that possibly formed as the result of methanogenic ^{12}C -rich gas production, the incorporation of the methane into the biomass of methanotrophic bacteria and inevitably the preservation of ^{12}C -enriched organic matter (Hayes, 1983).

Summary

Banded iron formations (BIFs) have been studied for decades in regard to their importance as an economically

viable source of iron ore, but their significance also extends to their potential as archives of the early Earth environment.

In spite of this effort, the mechanism of their deposition and in particular whether microorganisms drove the precipitation of BIF minerals, is still uncertain. Increasing evidence of a predominantly anoxic Earth until ~2.5–2.4 Ga forces the investigation of O₂-independent mechanisms for BIF deposition. For this reason, recent studies have explored the long-standing proposition that Archean BIFs may have been formed, and diagenetically modified, by anaerobic microbial metabolisms.

BASALT (GLASS, ENDOLITHS)

Ingunn H. Thorseth
 University of Bergen, Bergen, Norway

Synonyms

Endolithic microorganisms in basaltic glass; Microbial life in glassy basalt

Definition

Basalt endoliths. Microorganisms that colonize and live inside fractures, vesicles, and other cavities in basaltic rocks.

Basalt. The most common volcanic rock formed by eruptions of magma of basaltic composition.

Seafloor basalt. Basalt that is exposed at the seafloor, most commonly in or close to the ocean spreading ridge axes where the crust is young, or at intraplate seamounts.

Subseafloor basalt. Basalt that has been buried by younger lava flows and/or deep-sea sediments, as the crust aged and moved away from the spreading ridges.

Basaltic glass and endolithic microorganisms

Introduction

Basalt is continuously formed during volcanic eruptions along the global mid-ocean ridge system, and constitutes the upper 0.5–1 km thick layer of the ocean crust which covers more than 50% of the Earth's surface. When the basaltic magma is extruded into the cold seawater, the 1–2 cm thick outermost surface layer is cooled so rapidly that its chemical species do not have enough time to be arranged into minerals, but freeze to an amorphous glass rind. These glassy margins become heavily fractured due to cooling-related contraction, and the fracture networks provide an immense surface area for rock-water interactions and colonization by microorganisms. As the basaltic glass dissolves and alters more quickly than the minerals (pyroxene, plagioclase) in the crystalline interior of the lava, the glassy proportion plays an important role in the alteration of the ocean crust and the chemical exchange with the ocean water. The alteration is not only controlled by physiochemical factors but also by microbial processes, implied by the presence of endolithic microorganisms (see *Endoliths*) within the glassy margins. The microbial

activity may, on the other hand, be controlled by the geological environment, which includes a variety of complex fluid temperature and chemistry conditions ranging from seafloor weathering to various hydrothermal systems.

Basaltic glass alteration

Low-temperature alteration of basaltic glass results in the formation of concentrically zoned rims of a yellow-brown, hydrous residual alteration product, frequently called palagonite, along the outer surfaces, and internal vesicles and fractures of the glassy margins of lava flows. The altered glass is amorphous (gel-palagonite) to poorly crystalline with clayish character (fibro-palagonite) (e.g., Stroncik and Schmincke, 2001), and is usually highly enriched in oxidized Fe and Ti, and depleted in Si and alkaline and alkaline earth elements compared to the fresh, parental glass. The term palagonite was used for the first time by von Waltershausen in 1845 for the brown groundmass of a tuff from Palagonia, Sicily, and was then thought to be a new mineral phase. Although palagonite was later shown to be a heterogeneous material, the term has commonly been used in the literature. However, several authors now recommend referring to this material as altered glass. During the last 2 decades, various field and laboratory studies have shown that the alteration rate and the chemical and crystalline characteristics of the altered glass strongly depend on the physiochemical and hydrological conditions (e.g., Crovisier et al., 2003). The understanding of how the endolithic microorganisms in the glassy margins of basaltic lava flows influence and interact with the alteration process is, however, still poor.

Evidence of microbial life in glassy basalt

The first in situ observations of endolithic microorganisms in basaltic glass was reported from a scanning electron microscopy (SEM) study of recent (<1 million years old (Ma)) volcanic glass deposits from Iceland (Thorseth et al., 1992). Microbial biofilms together with irregular alteration fronts at the fresh-altered glass boundary lead to the suggestion that the degradation of the volcanic glass could be biocatalyzed by the development of more aggressive microenvironments in the near vicinity of the microbial cells. This was subsequently supported by experimental alteration studies, where development of corrosion marks in the glass surface only was observed in combination with biofilm formation and not in sterile controls (Thorseth et al., 1995a; Staudigel et al., 1995, 1998). Similar alteration textures resembling microbial cell morphologies observed in glassy margins of 6 Ma ocean basalt, sampled 432 m below the seafloor at the Costa Rica Rift during the Ocean Drilling Program (ODP) Leg 148, were then stained using DNA-specific dyes to confirm the presence of DNA within these structures (Thorseth et al., 1995b; Giovannoni et al., 1996; Furnes et al., 1996). Further fluorescence in situ

hybridization (FISH) were used to document the existence of indigenous Bacteria (see *Bacteria*) and Archaea (see *Archaea*) in this glassy basalt (Torsvik et al., 1998). Additional evidence for microbial activity in oceanic basalt came from the demonstration of carbon and nitrogen enrichments in the alteration textures (Giovannoni et al., 1996; Torsvik et al., 1998), and stable carbon isotope fractionation from disseminated carbonate that is consistent with microbial processes (Torsvik et al., 1998). During the last decade, further morphological, geochemical, biomolecular, and cultivation studies of seafloor and subseafloor basalts of various ages, water depths, depth of burial and temperature regimes, as well as of hydrothermal fluids, have revealed that diverse endolithic microbial communities colonize the upper oceanic crust at the spreading ridges. In addition, detection of comparable alteration textures and geochemical and isotopic biosignatures (see *Biosignatures in Rocks*) in lava margins of ancient oceanic basalt implies that microbial life and associated biodegradation in the ocean crust occurred very early in the Earth's history (Furnes et al., 2004; Staudigel et al., 2006).

Microbial life in seafloor basalt

Several electron microscopy studies of seafloor lavas from the Arctic Mohs and Knipovich Ridges and the Australian Antarctic Discordance (AAD) area of the Southeast Indian Ridge (SEIR) have demonstrated that a diverse and numerous endolithic microbial community of various coccoid, rod-shaped, filamentous, and stalked cells colonize the fracture network in the glassy margins of the basalts soon after its formation and exposure to the cold, oxygenated seawater (Figure 1) (Thorseth et al., 2001, 2003; Kruber et al., 2008a, b). The presence of microbial cells in lavas from different regions of the seafloor suggests that microbial colonization and growth is a general feature of mid-ocean ridge basalts. In very young basalts (0 Ma), the microbial cells are observed in the central fractures attached to the outer surface of alteration rims, within porous zones in the rims, and at the alteration front attached to the fresh glass (Figure 1b and c). The cells act as nucleation sites for precipitation and become encrusted and embedded in the secondary alteration products with time. Alteration rims where porous zones containing numerous hollow, apparently fossilized cells (see *Microbial Biomineralization*), alternate with compact zones lacking distinctive cell structures, indicate that the microbial growth in the fractures is discontinuous (Figure 1b). In older (2.5 Ma) seafloor basalts where the alteration rims are much thicker, no evident cell structures have been observed at the alteration fronts (Figure 1d), but occur in porous zones of the rims closer to the central fracture, and within in the fractures attached to secondary zeolite crystals (Figure 1e). The cells within the rims are much lower in carbon than those in the fractures, indicating that they are fossilized or partially decayed. This implies that

the fluid availability decreases through the alteration rims, away from the fractures (Thorseth et al., 2003).

Biomass

The presence of abundant alteration rims with closely packed microbial cell structures indicate high cell numbers in the glassy margins of young seafloor basalt. However, a significant fraction of these structures are fossilized cells that have accumulated through time. Thus, while the number of living cells measured by real-time quantitative PCR and fluorescence microscopy is estimated to be around 10^6 cells/g of glassy seafloor basalt (Einen et al., 2008), calculations based on the organic carbon content in the altered glass indicate a considerable larger endolithic biomass (around 10^9 cells/g of glassy basalt, assuming 10^{-13} g of carbon in one cell and that 1% of the glass is altered (Kruber et al., 2008a)). Even if this calculation is highly tentative, the discrepancy suggests that the biogenic material in the fossilized cells is preserved for some time before it is completely decayed. This is further supported by detection of carbon in individual cell encrustations by microanalytical techniques (Thorseth et al., 2003). Due to the highly porous and fractured character of the upper extrusive basalt layer at spreading axes, it is supposed that a similar biomass may also be present in the subseafloor basalt at depths down to several tens to hundreds of meters.

Phylogenetic and metabolic diversity

The endolithic microbial communities in the Arctic seafloor basalts are shown to be almost exclusively from the domain *Bacteria*, and only small proportions are from the *Archaea* domain (Einen et al., 2008). The most frequently retrieved bacterial DNA sequences from these basalts affiliate with the *Gamma-proteobacteria*, *Alpha-proteobacteria*, *Chloroflexi*, *Firmicutes*, and *Actinobacteria*, while the archaeal sequences were restricted to the marine Group 1 *Crenarchaeota* (Lysnes et al., 2004a). The phylogenetic diversity of basalt endoliths is found to be distinct and different from those observed in the surrounding deep seawater.

In contrast to deep-sea sediments where biogenic debris from the photic zone provides an important energy and carbon source for the inhabiting microbial communities, the basaltic basement is rich in reduced inorganic compounds that together with dissolved inorganic carbon may support growth of lithoautotrophic (see *Chemolithotrophy*) microorganisms (Bach and Edwards, 2003). Mid-ocean ridge basalts typically have iron contents of 7–9 wt%, of which approximately 80% is in the divalent state. As the basaltic glass alters to palagonite, Fe(II) is predominantly oxidized to Fe(III). The alteration of the glass may thus provide both potential energy and electron acceptors for the endolithic microbial communities. Observations of branching, twisted filamentous structures resembling stalks of the neutrophilic, iron-oxidizing bacteria (see *Fe(II)-Oxidizing Prokaryotes*) *Gallionella*

Basalt (Glass, Endoliths), Figure 1 Scanning electron microscopy images of seafloor basalts. (a) Glassy margin of zero-age basalt from the Mohs Ridge with typical network of cracks and fractures where the glass reacts with the seawater and alters to palagonite; (b) close up of fracture with regular alteration rims at both sides, showing alternating solid and porous zones with abundant cell encrustations (hollow spheres); (c) microbial cells attached to the fresh glass at the alteration front in the Arctic seafloor basalt; (d) interface between fresh and altered glass in 2.5 Ma seafloor basalt from the SEIR, where no evident cell structures occur; (e) zeolite crystal in fracture of the 2.5 Ma basaltic glass with clusters of coccoid cells attached to it; (f) filamentous structures resembling stalks of iron-oxidizing bacteria (see *Gallionella*) within fracture of zero-age basaltic glass from the Knipovich Ridge.

ferruginea (see *Gallionella*) and the newly characterized *Mariprofundus ferrooxidans* (Emerson et al., 2007) at the glass-palagonite interface (Figure 1f) indeed indicate that microbial oxidation of Fe(II) from the dissolving glass is associated with the weathering of basalt (Thorseth et al., 2001). Culturing of novel Fe-oxidizing lithoautotrophs from inactive sulfide chimneys (Edwards et al., 2003) furthermore suggests that other, previous unknown Fe-oxidizing species could occur in basalt as well. In addition, preferential accumulation of manganese in some cell encrustations can be explained by the activity of Mn-oxidizing bacteria (Thorseth et al., 2001, 2003; Kruber et al., 2008a, b). Isolation of numbers of diverse heterotrophic Mn(II)-oxidizing bacteria from the surfaces

of recent basalt flows from the Loihi Seamount strongly support this (Templeton et al., 2005). Results from DNA analyses and enrichments have furthermore shown that Fe-reducing bacteria (see *Fe(III)-Reducing Prokaryotes*) affiliating with *Shewanella frigidimarina* (see *Shewanella*) as well as other unknown Fe-reducers also are associated with the weathering of glassy seafloor basalt (Lysnes et al., 2004a). Microbial catalyzed cycling of Fe (and Mn) may thus be important in low-temperature alteration of oceanic basalt. Although seafloor basalts are in direct contact with the ambient, oxygenated seawater, the presence of microaerophilic microorganisms such as *G. ferruginea* and *M. ferrooxidans* demonstrates that redox-gradients are formed in the seawater-filled fractures

during an early stage of alteration and microbial colonization of glassy margins. The detection of Fe-reducers furthermore indicates that anaerobic microenvironments locally develop in the fracture network of the glassy margins. Neither sulfate reducing bacteria (SRB) nor secondary sulfide phases, which are commonly reported from marine sediment, have however, been detected.

Production of methane from hydrogen and carbon dioxide during enrichments indicates in addition that lithotrophic methanogens are present in glassy seafloor basalt, although DNA sequences from basalt and enrichments have not matched DNA sequences from any known methanogens (Lysnes et al., 2004a). The hydrogen source for methanogenesis in the basaltic glass is however, unclear. Degassing from deep magma chambers or production by high-temperature water-rock interactions associated with volcanic eruptions and serpentinization of ultramafic rocks (Holloway and O'Day, 2000; Kelley et al., 2002) are all unlikely processes at the actual sampling sites. Simulations of geochemical reactions between water and ultramafic rocks indicate, however, hydrogen production also at low temperatures (Palandri and Reed, 2004). Hydrogen production during low-temperature alteration of basalt has, however, been a matter of debate (e.g., Andersen et al., 1998). Hydrogen could, on the other hand, be produced by microbial processes.

Microbial impact on the alteration: biomineralization and microbial mediated dissolution

The microbial catalysed oxidation and reduction of iron and manganese, and nucleation and precipitation of alteration products on the microbial cells and their extracellular material, are likely to partially control the mobility of elements from the dissolving glass and reacting seawater. In addition, as the microbial growth and fossilization are main controls on the porosity and texture of the alteration rims, these processes are also expected to affect the fluid exchange rate and thus, the dissolution rate in the fractures. Together with the relatively large endolithic biomass, this suggests that the potential microbial impact on the weathering of seafloor basalt and the chemical exchange with the seawater is significant. Observation of pit marks in the glass beneath the attached microbes

(Figure 2a) furthermore suggests that the dissolution of the glass is to some extent controlled by microbial processes (Thorseth et al., 2001). It is, however, not known if the pitting is actively caused by local enhanced microbial dissolution due to the utilization of energy or nutrients present in the glass, or to the passive accumulations of metabolic waste products and the development of corrosive microenvironments at the interface between the microbial cells and the glass. Results from recent laboratory experiments have shown that organotrophs (Daughney et al., 2004) as well as lithoautotrophs (Edwards et al., 2004) have the potential to increase the dissolution rate and the alteration of basalt at the seafloor.

In addition to putative microbial mediated pitting, pit marks of similar form and size to microbes that are filled by hemispherical alteration structures and not by characteristic hollow cell encrustations (Figure 2b) suggest that abiotic processes may produce comparable dissolution textures to microbial processes. Such abiogenic corrosion marks most frequently occur in narrow fractures, which suggest that they are related to dissolution at low water-rock ratios (Kruber et al., 2008a).

Microbial life in subsurface basalt

Drill cores: textural, geochemical, isotope, and biomolecular biosignatures

The first reported evidence of endolithic microbes in basalt from the Costa Rica Rift subsequently stimulated to additional studies of basaltic glass in subsurface rocks from various locations and ages. Most of the studies report of similar textural, geochemical, isotope, and biomolecular evidences for microbial activity in the glass, as in the first report (Furnes and Staudigel, 1999; Fisk et al., 1998, 2003; Furnes et al., 1999, 2001a, b, 2003; Banerjee and Muehlenbachs, 2003; Thorseth et al., 2003; Benzerara et al., 2007). The phylogenetic and metabolic diversity of subsurface endolithic microbial communities inhabiting oceanic basalts have, however, only been described in the study by Lysnes et al. (2004b), and with more limited data in the study by Fisk et al. (2003).

While abiotic alteration of isotropic basaltic glass is expected to produce regular zoned alteration rims with

Basalt (Glass, Endoliths), Figure 2 (a) Pit marks in the glass with similar form and size as the attached microbial cells; (b) pit marks in the glass that are filled by solid hemispherical alteration structures and not by hollow microbial encrustations.

smooth interfaces between the fresh and altered glasses, the commonly observed irregular alteration fronts have been interpreted to be a result of enhanced dissolution or corrosion mediated by endolithic microbial cells. The most frequently putative biogenic alteration textures reported are (1) irregular patches or zones of individual or coalesced spheres with diameter around 1 μm (also characterized as a granular texture type), and (2) channels or tubular forms 1 μm to few μm wide and up to more than 100 μm in length (Figure 3). After the first reports of DNA-specific staining of altered glass from the Costa Rica Rift, similar textures in samples from other locations have also been shown to contain nucleic acids by fluorescent dyes (Furnes et al., 2001a; Banerjee and Muehlenbachs, 2003; Fisk et al., 2003), as well as elevated amounts of carbon, nitrogen, and phosphorus.

Using alteration textures as discriminating criteria, the extent and importance of biogenic versus abiotic alteration in the oceanic basement has been estimated. Thus, bioalteration has been observed in glasses from 0 to 170 Ma crust at 0–1.5 km depths of burial of lava flows and deep-sea sediments (Fisk et al., 1998; Furnes and Staudigel, 1999; Furnes et al., 2001b; Staudigel et al., 2006). The degree of this bioalteration is highly variable in the upper 300 m of the crust (20–90%), but tends to decrease with depth. The granular texture is found to dominate at all depths. The tubular texture only represents a small fraction of the total bioalteration, and is more common at deeper levels (Furnes and Staudigel, 1999; Furnes et al., 2001b; Staudigel et al., 2006).

The stable carbon isotope composition ($\delta^{13}\text{C}$) of disseminated carbonate provides additional evidence for endolithic microbial activity in altered oceanic basalts. Most investigated samples show $\delta^{13}\text{C}$ values that are significantly lower than magmatic carbon (5 to 7), indicating microbial utilization and oxidation of organic carbon which leads to ^{12}C -enriched CO_2 and carbonate minerals (Furnes et al., 2001a). Positive $\delta^{13}\text{C}$ values of some samples from the Atlantic Ocean have, on the other hand, been explained by lithoautotrophic utilization of H_2 and CO_2

and production of methane. During this process ^{12}C -enriched methane is lost, and the remaining carbonate is enriched in ^{13}C . This could result from more extensive serpentinization and abiotic formation of H_2 at the slow-spreading Atlantic ridge compared to other faster spreading ridges.

Despite the evidence for ongoing microbial activity in subseafloor basalt, few direct observations of evident microbial cell structures, which are easily observed in seafloor basalt, have been reported. Possible candidates are hollow and solid filamentous structures detected in basalt tuff recovered from the Ontong Java Plateau during the ODP Leg 192 (Banerjee and Muehlenbachs, 2003), and hollow spherical structures in pillow basalt recovered from the AAD area of the SEIR during ODP Leg 187 (Thorseth et al., 2003). However, these structures were all supposed to represent fossilized cells.

Petrographic inspection of samples drilled from 14 to 28 Ma ocean crust in the AAD area during the ODP Leg 187 indicated mostly low-temperature, oxygenated alteration conditions. Comparison of 2.5 Ma seafloor basalt from the same area with the much older subseafloor basalt indicated that a significant proportion of the glass alteration developed prior to burial. However, diffuse and highly irregular fresh-altered glass interfaces were only observed in the subseafloor samples and thus most likely developed after burial. These diffuse alteration fronts are apparently caused by dissolution and alteration of the glass into minute globules (0.05–0.2 μm in diameter), and no evident microbial cell structures could be observed to be associated. Some hollow, Mn-containing spherical structures that were observed within zeolite-filled fractures in one sample could represent fossilized equivalents of Mn-rich encrusted, apparently active microbes, observed in 2.5 Ma seafloor basalt (Figure 1e). However, the presence of few cell-like structures in the subsurface glassy basalt suggests that most of the numerous encrusted and fossilized cells developed during the surface stage are totally destroyed or masked by alteration and mineralization during burial. The fossilized cells within zeolite-filled

Basalt (Glass, Endoliths), Figure 3 (a) Petrographic thin section of basaltic glass from Costa Rica Rift, showing tubular structures at the alteration front of palagonite rim along a fracture; (b) close up of A; (c) DNA-specific DAPI staining (blue color) of the tubular structures, indicating the presence of DNA-containing cells.

fractures in subseafloor basalt, on the other hand, possibly indicate that microbial activity continued in the fractures after burial, for as long as circulation continued.

Pit marks and development of irregular alteration fronts both with and without the presence of microbes, and ambient fractures where smooth alteration interfaces are combined with numerous microorganisms attached to the fresh glass, as observed in seafloor basalt, together with irregular alteration fronts without detectable cells in subseafloor basalt, imply that great care should be taken before using alteration textures as the only criterion for microbial activity. Clearly, much more detailed knowledge is needed to fully understand the mechanisms that control both biotic and abiotic pit mark formation in basaltic glasses.

Drill cores: genetic and metabolic diversity

Drilling of 14–28 Ma ocean crust during ODP Leg 187 was partly aimed at studying the genetic and functional diversity of the subsurface microbial community (Christie et al., 2001; Pedersen et al., 2004; Lysnes et al., 2004b). Despite the sparse detection of only fossilized cells by SEM (Thorseth et al., 2003), the identification of a microbial community in these samples by biomolecular techniques that differ from that of surface seawater used as drilling fluid, document the presence of living cells in this old, sediment buried ocean floor basalts, and demonstrate that water-rock interactions also support a diverse endolithic microbial community in old ocean crust. This microbial community is probably present in fluid transporting fractures developed during tectonical events after burial. The nondetection of microbial DNA in a significant proportion of subseafloor samples could thus reflect not only a lower biomass in subseafloor basalts, but also a low number of open fractures in the samples analyzed, compared to seafloor lavas where DNA was retrieved from nearly all investigated samples (Lysnes et al., 2004a, b).

A major fraction of the endolithic microbial community in the subseafloor basalt from the ADD area was shown to be from the domain *Bacteria*, similar to the Arctic seafloor basalt. The five phylogenetic classes *Gamma-proteobacteria*, *Actinobacteria*, *Bacteroidetes*, *Chloroflexi*, and *Firmicutes* that were present in the seafloor basalt were also present in the old subseafloor basalt. The main differences observed were the higher frequency of *Gamma-proteobacteria* in subseafloor basalt, the restricted presence of *Alpha-proteobacteria* in seafloor basalt, and *Beta-proteobacteria* in subseafloor basalt. Fewer and more unequal distributions of the phylotypes in subseafloor samples suggest a decrease in biodiversity and biomass with burial and aging of the crust. The results from this study furthermore indicate that microbial communities inhabiting nonhydrothermal subseafloor basalts participate in the cycling of iron and in the production of methane from H_2 and CO_2 . A major part of the microbial populations showed no close relation to previously characterized microorganisms. The correspondence between

the microbial populations in nonhydrothermal seafloor (Lysnes et al., 2004a) and subseafloor basalts (Lysnes et al., 2004b) may reflect the low-temperature and oxidised conditions, as indicated by the secondary alteration phases and their chemical composition, in both environments. The genetic and physiological diversity of microorganisms in the nonhydrothermal oceanic basalt from the AAD area differ from those reported from hydrothermal fluids from hydrothermal active regions of the ocean crust.

Recently, evidence of the presence of also eukaryotic, fungal life in oceanic basalt was reported (Schumann et al., 2004). The filamentous structures, suggested to represent fossil fungi, were observed within carbonate-filled vesicles in 46 Ma subseafloor basalt recovered during the ODP Leg 200 in the Pacific ocean. These findings imply that fungal life may possibly still exist in the subseafloor basaltic environment.

Hydrothermal fluids

Several studies of the microbial diversity in hydrothermal fluids (see *Hydrothermal Environments, Marine*) associated with eruptions in the central volcanic active zone of spreading ridges have been carried out during the last years (Summit and Baross, 1998, 2001; Huber et al., 2002, 2003). These studies have shown that the vent fluids inhabit microorganisms that are different from indigenous seawater microorganisms, suggesting that the vent fluids carry endolithic microbial cells from the basaltic subsurface environment. In the studies by Huber et al. (2002, 2003) dominant subseafloor phylotypes affiliated with the *Alpha*-, *Gamma*-, *Delta*- and *Epsilon-proteobacteria*, *Firmicutes*, novel candidate divisions, Group I *Crenarchaeota*, and Group II *Euryarchaeota* were detected. Most of these phylotypes were reported to be unique, differing from those of surrounding seawater, and affiliated with both low- and high-temperature groups. Considerable overlap with seawater was only found within *Alpha*- and *Gamma-proteobacteria*. To explain the retrieved diversity, Huber et al. (2003) proposed a schematic model of the basaltic subseafloor at the sampling site, based on hydrothermal fluid and seawater mixing that included three different compartments: a deep, anaerobic zone dominated by the hot hydrothermal fluid that contains mostly thermophilic microorganisms; an intermediate zone with both seawater and hydrothermal fluid and the highest variability in microbial community composition, probably including anaerobes, aerobes, and microaerophilic organisms; and an uppermost low-temperature, aerobic zone that is seawater-dominated, possibly containing seawater organisms. Unique subseafloor microorganisms flushed out from this uppermost zone by the vent water could thus be similar to microorganisms detected in nonhydrothermal basalts. Some of the *Gamma*- and *Epsilon-proteobacteria* sequences retrieved from both nonhydrothermal seafloor and subseafloor samples (Lysnes et al., 2004a, b) were phylogenetic affiliated

to sequences retrieved from the <50°C diffuse flow vent fluids associated with an eruptive event on the Juan de Fuca Ridge (Huber et al., 2003).

Investigation of 65°C subsurface fluids from aging (3.5 Ma) ocean crust by Cowen et al. (2003) also demonstrated the presence of a diverse bacterial and archaeal community in hydrothermal active areas of the mid-ocean ridge flanks. In this reduced, hydrothermal environment DNA sequences related to the ammonia-producing *Ammonifex degensii* and sulfate reducers of the *Delta-proteobacteria*, the low G + C Gram-positive genus *Desulfotomaculum*, and *Archaea* (*Archaeoglobus*) were dominant. A later study of 20°C subseafloor fluids from the same area demonstrated that the microbial community in the fluids composed of species indigenous to the subseafloor, as well as species from seawater and sediments (Huber et al., 2006). No sequences retrieved from nonhydrothermal seafloor and subseafloor basalts resembled those obtained from these 65°C subseafloor fluids.

Using available published 16S rDNA sequences from basalt, hydrothermal fluids, basalt enrichments, and data from other relevant environments, Mason et al. (2007) examined the phylogenetic diversity of microbial communities associated with marine basalts. Based on these data, it was suggested that the microorganisms have a cosmopolitan distribution. Most groups were found in both basalts and sediments, but are distinct from microbes in other marine habitats. One group of Marine Group I *Crenarchaeota* seems furthermore to be specifically adapted to basalt.

Biosignatures in ophiolites and greenstone belts

During the last years, terrestrial fragments of ancient ocean crust (ophiolites) and greenstone belts have been investigated for similar biosignatures as those observed within in situ oceanic basalt. For example, the results from the well-preserved ~90 Ma Troodos ophiolite in Cyprus revealed comparable traces of microbial life in the glassy lava margins as reported from studies of in situ oceanic crust, except for DNA that could not be detected by specific staining (Furnes et al., 2001c). This, together with geochemical and isotope data indicative of seawater alteration under oxidizing condition, imply that the main fraction of the alteration occurred prior to obduction during an early stage of ocean-floor alteration. Comparable textural, geochemical, and isotopic data obtained from lava margins from the ~3.5 billion-year-old Barberton greenstone Belt in South Africa further suggest subaqueous microbial activity during the early history of the Earth (Furnes et al., 2004) (see *Early Earth*). Thus, these biosignatures could be of great relevance in the search for life elsewhere in the universe (see *Astrobiology*).

Conclusions

Endolithic microbial communities have been documented in glassy margins of seafloor and subseafloor basaltic lavas from various locations of the ocean crust. In seafloor

basalt the microbial cells are easily recognized by electron microscopy, and are shown to be closely associated with the alteration of the glass. In subseafloor basalt the microbial activity has mainly been recognized by the use of biosignatures such as characteristic cell-like alteration textures in the glass, elevated concentrations of carbon and nitrogen in these textures, and stable carbon isotope ratios of disseminated carbonate consistent with biological processes. DNA-specific staining indicates the presence of DNA in the cell-like alteration textures. Culturing and biomolecular studies have revealed the existence of diverse, endolithic microbial communities in the glassy margins of oceanic lavas. The results suggest that iron and manganese cycling are important microbial processes in cold, nonhydrothermal regions, while sulfur cycling plays a major role at elevated temperatures in hydrothermal active areas. The endolithic microbial life in oceanic basalt may have a significant impact on the alteration of the basalt and the chemical exchange between the ocean crust and seawater.

 Bremen, Germany

Definition

Beggiatoa is a colorless, sulfur-storing bacterium belonging to the Gammaproteobacteria, filamentous, motile, and not attached.

Bacteria of the genus *Beggiatoa* live by the oxidation of sulfide with oxygen or nitrate. They are benthic

Beggiatoa, Figure 1 *Beggiatoa* filaments of 6 μm diameter seen under the light microscope with dark field illumination. The sulfur globules reflect the light and give the filaments their shining white appearance.

organisms, which occur in almost all freshwater and marine environments where sulfide is present, e.g., wastewater, areas of coastal upwelling, salt marshes, hydrothermal vents, cold seeps, methane hydrates, etc. In contrast to most bacteria, *Beggiatoa* can be recognized by its typical morphology. It is a filamentous bacterium, which is motile by gliding and stores elemental sulfur inside, giving it a shining white appearance (Figure 1). The filaments can be several millimeters to centimeters long and are formed by long rows of cells with diameters between 1 and 200 μm . The larger species of *Beggiatoa* (>5–10 μm in diameter) have a central vacuole, which they use for storing nitrate in high concentrations (ca 10–300 mM).

Beggiatoa filaments typically occur as mats on top of the sediment or within the upper few centimeters. They actively glide to the overlapping zone of oxygen, supplied from the open water, and sulfide evolving in the sediment. In addition to oxygen, the larger species can also use internally stored nitrate for the oxidation of sulfide and thereby increase their rates of sulfide oxidation or survive periods of anoxia. Sulfide is first oxidized to sulfur, which forms intracellular sulfur globules, and then further on to sulfate. If sulfide concentrations are high, the cells are filled with many sulfur globules, which are disappearing in the absence of sulfide. Apart from sulfur and nitrate, *Beggiatoa* filaments were also observed to store polyphosphate and poly-beta-hydroxybutyrate (PHB).

Definition

Biodeterioration: Undesirable alteration of the properties of materials caused by vital activities of organisms.

Introduction

Materials are exposed to weathering processes caused by physical, chemical, and biological factors, leading to an irreversible loss of our cultural heritage. The reduction of decay by conservation strategies is of particular importance to protect historical monuments or significant cultural artifacts.

Generally, the velocity of decay depends on the chemical nature and physical structure of materials as well as external factors associated to the locations where the objects are exposed. In many studies it was demonstrated that the process of weathering consists of various mechanisms acting together in coassociation with more or less intensity, making it impossible to separate individual aspects such as physical, chemical, or biological factors from each other (Koestler et al., 1994; Ehrlich, 2002). In many cases microbial activities can accelerate or trigger physicochemical processes. But the composition of microbial consortia, rather the microbial activity, is also affected by the surrounding chemical and physical factors.

Solar irradiation, wind, and variations in temperature and humidity predominate the physical effects. Wind and humidity, of course, lead to the erosion of particles from stone surfaces. Variations in temperature, due to diurnal and seasonal changes, cause tensile stresses that can break up the structure of the material, resulting in a loss of persistence. Humidity, in combination with frost and salt, can intensify this effect. The crystallization of water or saline solutions is connected with an increase in volume that leads to “frost shattering” or “saline shattering” (Steiger and Dannecker, 1995).

Chemical weathering may be caused by rain water which dissolves carbon dioxide originating from the ambient air or from respiration of present microorganisms. Generated carbon acid reacts with calcium carbonate, thereby producing calcium hydrogen carbonate with a higher solubility than calcium carbonate (Bell, 1993).

According to Krumbein and Schönborn (1987), biological damages of building material can be divided into

different categories: (1) Anthropogenically induced damages due to atmospheric pollution as a result of the industrialization. These processes lead to an increasing level of inorganic (SO_2 , NO_x) and organic (aliphatic and aromatic hydrocarbons) compounds in the air. This implicates acid rain that has a corrosive effect on stone buildings or other exposed materials (Pitzurra et al., 2003; Winkler, 1987). (2) Damages caused by higher plants and animals. The growth of higher plants, for example, leads to the physical destruction of materials. Moreover, excrements of birds contain ammoniac and nitrite, which can be utilized by chemolithotrophic bacteria. (3) Microorganisms such as bacteria, algae, fungi, and lichens can cause a degradation of materials. These damaging effects will be specified below.

Furthermore, biological colonization and the intensity of associated biodeterioration processes are strongly influenced by water availability. This is determined by specific material parameters such as porosity and permeability, as well as by environmental conditions.

Microbial degradation processes

How do microbial associations interact within these complex weathering processes? A considerable amount of studies have been done to figure out the role of microbiological agents in weathering processes (e.g., Urzi and Krumbein, 1994; Griffin et al., 1991; Warscheid and Braams, 2000). Generally, microorganisms play an important role within the regulation of the global cycles of materials, contributing to the function of the ecosystems. However, microorganisms also play a crucial role concerning the stability of materials. The interactions between microbial associations and materials can be divided into three different categories (Weber, 1993, cf. Figure 1): (1) The material can be decomposed enzymatically and used as a nutrient source by microbial associations. (2) Microorganisms can excrete metabolic compounds such as inorganic and organic acids that interact with mineral compounds of the material, thus causing dissolution and discoloration. (3) The material can be damaged by physical (mechanical) forces due to the growth of microorganisms.

For the most part, microorganisms conglomerate to biofilms of different natures such as crusts, fluffs, or slime, giving them the ability to colonize nearly all biotic and abiotic surfaces (Costeron et al., 1987). Biofilms can exhibit a highly spatial structured composition (Stoodley et al., 2002), thereby consisting of different prokaryotic and/or eukaryotic populations, extracellular polymeric substances (EPS), accumulated polyvalent cations, as well as solvated and dissolved organic and inorganic particles. The formation of biofilms provides considerable advantages including mechanical stability, the facility of symbiotic and syntrophic interactions, the building of a diffusion barrier and an increased resistance against toxic environmental conditions, biocides, aridity, or pH variabilities (Wolfaardt et al., 1999). However, the presence of biofilms can lead to biophysical determined damages of

Biodeterioration (of Stone), Figure 1 Interactions between materials, environmental conditions, and subaerial biofilms include (1) atmosphere substrate interactions (2) interactions between atmosphere and biofilms (3) interactions of metabolic compounds and substrate; enzymatic degradation (4) physicochemical interactions between biofilm and substrate (5) physical forces due to microbial growth.

surface structures of stone (Gorbushina and Krumbein, 2000; Gorbushina, 2007). Variations in temperature and humidity induce shrinking and swelling cycles of the film, leading to an alteration of hydrophobic–hydrophilic properties of rock surfaces. As a consequence, hydrophobic properties of stone surfaces can turn into hydrophilic.

Microorganisms involved in biodeterioration processes

The ecology of microbial associations colonizing rocks is highly complex and involves different groups of microorganisms with different physiological properties. These ecosystems can develop in various ways, depending on environmental conditions and physicochemical properties of the material. Therefore, only a small range of examples can be discussed in this framework, representing the complexity of the interactions between microorganisms and their substrate.

Phototrophic microorganisms

Phototrophic microorganisms such as algae, cyanobacteria and lichens, but also mosses and even higher plants cover stone surfaces, thus changing the face of new buildings or cultural heritage. In many cases they form biofilms or crusts to protect themselves from unfavorable environmental factors. These crusts or films can appear in a deep or light green color under humid conditions or in black tint under dry environmental conditions (Urzi and Krumbein, 1994; Krumbein and Warscheid, 1992). Under particular

climatic conditions (e.g., tropical environments) these biofilms provide a protective effect, isolating the stone surface from aggressive environments and regulating humidity and temperature (Krumbein and Warscheid, 1992). But the formed biopatina can also cause damages by physical and chemical processes (Krumbein and Warscheid, 1992; De los Rios et al., 2009). Associated biodeterioration processes can be induced by the excretion of corrosive acids (Arino et al., 1997), the uptake of substrate compounds such as sulfur and calcium and accumulation into their cells (Orgenta Calvo et al., 1994), and by the alteration of stone forming minerals (Ortega-Morales et al., 2000; Crispim and Gaylarde, 2004). Finally, the penetration of hyphae and roots causes enlargement of pores and loosening of stone particles from the material (Ascaso et al., 1998). The formation of biofilms intensifies this loss of structural consistency (Orgenta-Calvo et al., 1991).

Due to the capability of fixing atmospheric nitrogen, phototrophic organisms are often the primary settlers of habitats especially in combination with fungi as lichens. In rural or strongly industrialized areas where the air is enriched with nitrogen from fertilizers or industrialization, their growth can be enhanced (Cadot-Leroux, 1996; Cicek et al., 2008). Some phototrophic microorganisms (epilithicphototrophs) may penetrate several millimeters into the stone pore system (Golubic et al., 1981). Additionally, some of these microorganisms can colonize extreme locations, whereby a special pigmentation protects them against strong light irradiation (Krumbein and Jens, 1981).

Chemolithotrophic and chemoorganotrophic microorganisms

Even the natural biomass accumulated by photosynthetic microorganisms – especially in combination with anthropogenic pollution – can serve as nutrient source for the establishment of heterotrophic microorganisms (Warscheid et al., 1991; Zanardini et al., 2000).

Besides, even without a primary settlement of phototrophic microorganisms an establishment of heterotrophic organisms is possible (Krasilnikov, 1949). A sufficient amount of inorganic compounds (e.g., sulfur, ammonium, sulfide) enables the appearance of chemolithoautotrophic bacteria (Kaufmann, 1960; Pochon and Jaton, 1967). The formation of nitrous acid (HNO_2 by *Nitrosomas*) or nitric acid (HNO_3 by *Nitrobacter*) and sulfuric acid (H_2SO_4 , *Thiobacillus*) results in the solution of mineral rock compounds. Acidic metabolic compounds resulting from the oxidation of sulfur, for example, interact with calcium carbonate of the stone structure. This reaction leads to the formation of calcium sulfate, which is more soluble than calcium carbonate.

The most numerous microorganisms in natural building stone are chemoorganotrophic bacteria. Results of Warscheid et al. (1993) indicate that they colonize natural stone within weeks. They can excrete acid compounds but, generally, their destructive activity has been evaluated as low (Lewis et al., 1988). Nevertheless, they are extensively involved in the formation of biofilms, thus causing physicochemical properties of the mineral structure described above. Materials can contain or be associated with organic compounds such as dust, natural resin, wax, or atmospheric aerosols that can act as nutrient source for chemoorganotrophic microorganisms (Warscheid, 1990). As an effect of organic pollution, chemoorganotrophic microorganisms can be the first settlers on buildings in highly industrialized locations (Krumbein, 1966). Many chemoorganotrophic bacteria are able to use low degradable compounds, offering nutrients for other microorganisms of the microbial consortia (Warscheid et al., 1991; Zanardini et al., 2000).

Fungi

The colonization of stone surfaces or other materials by fungi causes damages, especially by physical (mechanical) forces (cf. Figure 2). The formation of penetration hyphae enables some fungi to enter actively into materials, despreding within the material and affecting the so-called biopitting structures on rock surfaces (Sterflinger and Krumbein, 1997). Furthermore, the production of aggressive acidic metabolites leads to biocorrosion (Kurakov et al., 1999). In comparison to bacteria, fungi can establish rapidly, especially in environments with low humidity due to their widespread system of hyphae (Weber, 1993). Their damaging effects also include the discoloration of surfaces due to the building and excretion of melanins (Gorbishina et al., 1993). The synthesis of special pigments such as melanin, carotenoids, and mycosporines provides

Biodeterioration (of Stone), Figure 2 (a) Scanning electron microscopic demonstrate colonization of amber surface by recent microorganisms. Fungal hyphae cover the amber surface and accumulate in cracks leading to loss of material persistence by physical stresses; scale bar 100 μm . (b) closeup, scale bar 10 μm . (Reitner and Beimforde, 2008).

protection against UV radiation and enables some species (e.g., black fungi) to colonize even at locations with extreme UV radiation (Chertov et al., 2004).

Measures and preventive treatments

In general, a microbial colonization is primarily dependent on the availability of water and nutrients and specific material parameters such as porosity, permeability, architectural conditions (considering buildings), and environmental factors. Natural selective processes can lead to the formation of populations that reveal a perfect adaption between organisms, substrate, and environment. A previous individual and comprehensive analysis of all factors and relationships is essential before preventive treatments or cleaning of the material is applied. A mechanical cleaning of historical buildings from dust or biological films should integrate a chemical analysis to characterize the surface dirt. Otherwise, the cleaning procedure can fail to have a long-lasting effect and even accelerate the degradation processes or alteration within the composition of microbial associations affecting changes of microbial activity (Dornieden et al., 2000).

Water cleaning can help remove soluble salts and biological infections, but in the long term it can lead to a wider dispersion of the microbial infection because of increased humidity. Furthermore, consolidation treatments can be applied, but their effectiveness is strongly connected to the physical structure of the stones. The application on stone surfaces with insufficient consistence and absorbent capacity can intensify physical damages (Sattler, 1992; Wendler, 1992; Zoghalmi and Gómez-Gras, 2004). Other preventive agents impregnate surface structures and are often based on high polymer polysaccharide, silane, or siloxane. Various studies have shown that the application of consolidants or water repellents induce an increasing activity or colonization of microorganisms using these restoration agents as nutrient source (Krumbein et al., 1993; Petersen et al., 1991, cf. Figure 3). Studies of Urzi and

De Leo (2007) and De Leo and Urzi (2003) have shown that water repellents alone do not stop microbial colonization, but in combination with biocides, microbial growth can be prevented.

Finally, it is important to mention that the treatment with biocides should only be applied in instances where biodeterioration processes cannot be controlled and chemical applications are unavoidable. An inappropriate treatment with biocides or other preventive arrangements can lead to an increasing selective microbial colonization that may accelerate the deterioration.

Summary

The process of weathering consists of physical, chemical and biological factors acting together with more or less intensity, leading to an irreversible loss of our cultural heritage. Microbial activities can accelerate or trigger physicochemical processes. But the composition of microbial community or rather the microbial activity is also affected by the surrounding chemical and physical factors. Interactions between microbial associations and materials contain the enzymatic decomposition of materials, excretion of metabolic compounds such as inorganic or organic acids, and damages by physical (mechanical) forces due to the growth of microorganisms.

Definition

Bioerosion is defined as erosion, i.e., removal and transport of materials by the action of organisms. Bioabrasion refers to removal by mechanical means: scraping, rasping, drilling. Biocorrosion refers to removal by chemical means: etching, dissolving, boring. Bioerosion is often carried out by a combination of bioerosional tools. Bioerosion by microorganisms is referred to as microbioerosion as opposed to macrobioerosion performed by animals and plants. External bioerosion is carried out by organisms that live outside the substrate but remove it in the process of seeking food (grazing). Internal bioerosion is carried out by organisms that excavate the substrate for shelter and live inside as endoliths. They penetrate the substrate actively as euendoliths, or

occupy existing cavities as cryptoendoliths or fissures in the rocks as chasmoendoliths.

Concept of bioerosion

The concept of erosion is usually discussed in geology, particularly in geomorphology, sedimentology, and soil sciences, in reference to degradation and transport of rocks and sediments by environmental forces such as wind, water, or ice. The participation of organisms in these processes and their long-term geological impact are often ignored. The role of organisms in sediment stabilization, organization, and buildup is becoming increasingly recognized as biosedimentation, and so is bioerosion, i.e., the participation of organisms in destruction of rocks and sediments.

Similar to weathering and erosion by environmental forces, the destruction of hard substrates by organisms, i.e., biological erosion or bioerosion (Neumann, 1966) includes two mechanisms: (a) biological corrosion, which refers to destruction of substrates by chemical means introduced by organisms, thus promoting dissolution of solid substrates, and (b) biological abrasion, which refers to mechanical destruction and removal of substrate by organisms (Golubic and Schneider, 1979). Sediment particles are frequently produced during biological abrasion and are redeposited (Neumann, 1966; Schneider and Torunski, 1983).

Bioerosion affects various substrates, most commonly the relatively soluble ones such as carbonates, phosphates, and sulfates. Bioerosion of siliceous rocks occurs at much lower rates and is rarely conspicuous. The objects of bioerosion include solid rocks, sediment particles, and mineralized skeletons of various live and dead organisms. Bioerosion takes place in a wide variety of aquatic and terrestrial environments. Its effects are especially noticeable in coastal carbonate rocks, coral reef structures, and molluscan calcareous skeletons, but are less apparent in skeletons of live corals (Le Campion-Alsumard et al., 1995a), encrusting coralline algae (Pantazidou et al., 2000; Tribollet and Payri, 2001; Ghirardelli, 2002), foraminifera (Golubic et al., 1984), calcareous ooid sand particles (Al-Thukair and Golubic, 1991), and fish teeth (Underwood et al., 1999).

Many researchers describe penetration into hard substrate as boring activity, in contrast to burrowing, which describes digging into loose substrate such as sand and mud; however, some use the term burrowing for penetrating any substrate. Others suggested that activities of bioeroding organisms be distinguished on the basis of their objectives (e.g., food vs. shelter). Many bioeroding organisms are fully or partially embedded in the rocky substrate, occupying an endolithic habitat, while others erode the substrate from outside. Accordingly, they have been distinguished as internal versus external bioeroders. Many investigators view bioerosion as behavior (Boucot, 1990) and relate bioeroding organisms to the traces they leave in modern and ancient hard substrates. Researchers

employ a variety of experimental strategies and preparation techniques, including x-ray visualization (Bromley, 1970; Sammarco and Risk, 1990), replication (casting) of borings in polymerizing resins (Golubic et al., 1970), and digital imaging (Tapanila, 2008).

The research of geological history of bioerosion relies on traces left by bioeroding organisms in ancient sediments, so that the study of trace fossils constitutes a separate discipline with its own methods and rules of nomenclature. According to the rules of the International Code of Zoological Nomenclature (ICZN), which governs trace fossil investigations, the traces have to be named separate from the organisms that make them (Bromley, 1990; Bertling et al., 2006). These studies are published in special journals (e.g., *Ichnos*, *Facies*), and as proceedings of symposia and compendia (Carriker et al., 1969; Crimes and Harper, 1970; Frey, 1975; Bromley, 1990; Miller, 2007). The geological roles of bioeroding organisms are periodically reviewed regarding: (a) their diversity and evolution, (b) behavior, (c) recognition and classification of their traces and imprints in the substrate, (d) their impact on sedimentary systems, and (e) other environmental consequences of their activities (Hutchings, 1986; Radtke et al., 1997; Perry and Hepburn, 2008; Tribollet, 2008b). Bibliographies on past and present bioerosion are also displayed on line (see Cross-references below).

Agents of bioerosion

Agents of bioerosion cover a wide range of sizes. Organisms that actively penetrate hard substrates are for practical reasons treated separately as microborers (size <100 µm) and macroborers (size >100 µm). In addition to macro- and microboring organisms, which predominantly act as biocorroding agents (internal bioeroders), bioerosion is strongly affected by bioabrasion by various grazing invertebrate and vertebrate animals (external bioeroders). Predators able to penetrate shells and attack the animal inside constitute a special group of bioeroders that includes predatory snails and cephalopods (called “predators” in this chapter). Bioeroding organisms are metabolically diverse; they employ different feeding strategies and thus affect substrates differently. Some organisms penetrate or perforate hard substrates in search of food, such as fungi and predatory snails. Others penetrate the substrate and use it as a habitat while depending on external energy sources. This is the case with boring phototrophs, such as cyanobacteria, algae, and lichens as well as with filter-feeding invertebrates.

Organisms that occupy the interior of rocky substrates are called endoliths, as opposed to epiliths that adhere to external rock surfaces. At the microscopic scale, hard substrates provide different habitats, which are occupied by different endolithic microorganisms (Figure 1). Cracks and fissures in rocks are occupied by chasmoendoliths, the existing pore spaces between grains in sandstones or structural pores in skeletons are occupied by

Bioerosion, Figure 1 Microorganisms of a lithobiontic niche: Epiliths occupy the surface of the rock by forming a biofilm, mat, or turf, while endoliths occupy the interior of the rock: chasmoendoliths line the walls of cracks and fissures, cryptoendoliths fill preexisting textural spaces and pores within the rock, and euendoliths penetrate the carbonate substrate and live in the pores of their own making. (Modified from Golubic et al., 1981.)

cryptoendoliths; only euendoliths or microborers actively dissolve substrates and occupy spaces of their own making (Golubic et al., 1981).

The euendoliths are equipped with special chemical or mechanical means of bioerosion, although other inhabitants of the rock interiors may also affect the substrate by modifying the chemistry of the surrounding interstitial waters. Euendoliths, both micro- and macroborers, produce boreholes and tunnels in the substrate that comply closely to the outlines of their bodies (Pohowsky, 1978; Radtke and Golubic, 2005). At a finer scale, they leave etch marks that comply with and reflect crystalline composition of the rock (Golubic et al., 1975). Both, micro- and macroborings preserve well in the fossil record and provide valuable information about past environments (Vogel et al., 1987; Glaub et al., 2007; Bromley, 2004).

Microborers comprise phototrophs such as cyanobacteria and algae (mostly chlorophytes and rhodophytes) and organotrophs (heterotrophs) including fungi, foraminifera, and other, mostly unidentified prokaryotic and eukaryotic light-independent organisms.

Euendolithic cyanobacteria (Figure 2) include members of all orders, Chroococcales (coccoid forms) (Figure 2a–c), Oscillatoriales (non-heterocystous filamentous forms), Nostocales, and Stigonematales (unbranched and branched heterocystous filamentous forms) (Figure 2d). Euendolithic algae include septate and siphonal chlorophytes (Figure 3) and endolithic “Conchocelis” stages in the life cycle of some rhodophytes (Bangiales). Euendolithic fungi include lower (Chytrids) and higher fungi (Ascomycetes, Basidiomycetes), but many are known only by the borings they

Bioerosion, Figure 2 Common euendolithic cyanobacteria. produce (Figure 4). Euendolithic and partially endolithic mode of life is known for benthic foraminifera, including fossil forms, and their boring traces are common. However, little is known about the biology or taxonomic identity of euendolithic foraminifera (Bromley et al., 2007).

The mechanisms of carbonate dissolution in the process of penetration into rocky substrate by microbial euendoliths are poorly understood. The observed variations in boring behavior indicate the existence of different mechanisms, which may include calcium pumps (Garcia-Pichel, 2006), respiratory carbonic acid (Tribollet, 2008b), or enzymes such as carbonic anhydrase. Microborers are mainly agents of biocorrosion.

Macrobiorers include specialized sponges (Figure 5), such as clionids (Rützler, 2002), various groups of worms including polychaetes (Wielgus et al., 2006), phoronids (Plewes, 1994) and sipunculids (Gherardi and Bosence, 2001), and other invertebrates including ctenostome bryozoans (Pohowsky, 1978; Todd, 2000), acrothoracic cirripedia (barnacles) (Kolbasov, 2000), and bivalves, such as lithophagid mussels (Figure 6) (Scott and Risk, 1988; Kleemann, 1996).

Boring sponges employ the enzyme carbonic anhydrase for biocorrosion combined with mechanical cleavage of cell-size particles, which are expelled into the environment (Pomponi, 1980). The research on boring sponges was recently reviewed by Schönberg (2008). Polychaetes and pholadid mussels use a combination of chemical and mechanical means of penetration into rocks and shells. For example, polychaetes involve setae for mechanical removal of chemically loosened substrate, whereas the pholadid mussels use rotation movement of their shells (Hutchings, 1986).

Grazers are the principal agents of biological abrasion (external bioerosion), and comprise gastropods (Schneider and Torunski, 1983; Radtke et al., 1996), polyplacophores (Rasmussen and Frankenberg, 1990), echinoderms (Carreiro-Silva and McClanahan, 2001), and fish (Bruggemann et al., 1994), especially parrotfish on coral reefs (Hoey and Bellwood, 2008). Grazers are

not endolithic and they do not perforate shells. Instead, they remove layers of the mineral substrate with their specialized hard mouth parts (e.g., “Aristotle’s lantern” of sea urchins, magnetite-enforced radulas of snails and beak-like jaws of parrotfish) while feeding on epilithic algal turf and also removing external and internal microbial biofilms (Golubic and Schneider, 2003).

Predators that successfully attack invertebrates protected by shells include snails of the families Naticidae, Muricidae, and five other families (Walker, 2007), as well as foraminifera (Cedhagen, 1994). Predatory snails use a combination of mechanical and chemical means of making a perforation in the shell of their prey and killing the prey (Carriker, 1969). Euendolithic fungi, which grow inside coral skeletons, from where they regularly attack

Bioerosion, Figure 6 Pholadid bivalves penetrating the coral skeleton of *Porites*. Note that the hole is commensurate with the size and shape of the mussel. Scale bar is 1 cm long.

coral polyps, can also be considered predatory. Fungi may compromise the coral’s ability to overcome environmental stress conditions or to resist diseases inflicted by other causative agents (Le Campion-Alsumard et al., 1995b; Benthis et al., 2000).

Diversity of bioeroding organisms

The ability to exploit resources by eroding rocks and sediment particles evolved in various prokaryotic and eukaryotic groups of organisms, often enhanced by their mutual interactions. Microbial euendoliths contribute significantly to the overall benthic primary production and support a variety of grazing invertebrates and vertebrates. Their continuing activity, however, depends on grazing, which maintains optimal light access to rocky surfaces.

Microbial euendoliths or microborers are ubiquitous. They are distributed globally: in marine (Tribollet, 2008b), freshwater (Schneider and Le Campion-Alsumard, 1999; Anagnostidis and Pantazidou, 1988), and terrestrial environments (lichens) (Golubic and Schneider, 2003). However, they are most diversified in marine environments, where they occupy a variety of ecological niches that range in distribution from the supratidal coastal spray zone to the abyssal depths. Macroborers in carbonate substrates are predominantly marine. There are a number of predatory snails in terrestrial and freshwater habitat, but shell perforation is known only for marine species.

Bioeroding organisms are also highly diversified and specialized, so that different environmental settings, different latitudes and regions are settled by different species and genera. Their regional distribution based on taxonomic distinctions and evolutionary history is beyond the scope of the present article. Instead, we will concentrate on environmental conditions and constraints that determine distribution of particular assemblages of euendoliths and their traces, so that they can be used as environmental and, by extension, as paleoenvironmental

and paleobathymetric indicators (Golubic et al., 1975; Vogel et al., 1987; Glaub et al., 2001, 2007). Further we will present case histories that illustrate synergistic interactions among bioeroding organisms that resulted from their coevolution.

Depth distribution of microbial euendoliths

Light is a critical factor for depth distribution of phototrophic euendolithic organisms, whereas the organotrophs are light-independent and depend on organic food supply. Light is absorbed selectively by the water column as well by the organisms and their pigment systems. The combination of both defines the euphotic and disphotic environments, and triggers adaptations to different light intensities and spectral qualities, as well as responses to quantitative and qualitative shading, resulting in microbial arrangement in strata. Other factors, such as water supply and chemistry, including redox potential and nutrient availability pose further limitations, challenges, and opportunities to which the organisms respond.

The intertidal ranges of carbonate coasts are densely populated by assemblages of endolithic cyanobacteria (Le Campion-Alsumard, 1979). More than half a million euendoliths commonly occupy a square centimeter of limestone rock surface (Figure 7) (Schneider and Le Campion-Alsumard, 1999). Intertidal barnacles and mussels are also subject to cyanobacterial borings whenever the protective periostracum layer of their shells is damaged. Extensive boring by euendolithic cyanobacteria has been shown to inflict lethal damage on mussels by destroying their shells (Kaehler and McQuaid, 1999). An assemblage of intertidal cyanobacteria appears to have cosmopolitan distribution with characteristic morphotypes of *Hyella balani* (Figure 2b), *H. caespitosa*, *Plectonema terebrans*, *Mastigocoleus testarum* (Figure 2d), and *Kyrtuthrix dalmatica* (Figure 8), which

Bioerosion, Figure 7 Cylindrical boreholes produced by filamentous cyanobacteria oriented perpendicular to the surface of dead coral skeleton. Coral rubble in the intertidal range. Scale bar is 10 μ m long. (Compare scale bars in Figures 6 and 7).

are common on Mediterranean coasts (Le Campion-Alsumard, 1979; Le Campion-Alsumard and Golubic, 1985) and also on the coast of South Africa (Kaehler and McQuaid, 1999). Similar assemblages of euendolithic organisms and their traces have been found at different latitudes including northern seas (Wisshak et al., 2005), but their highest diversity and the highest rates of bioerosion have been recorded in lower latitudes (Wisshak, 2006; Tribollet and Golubic, 2005).

Special assemblages of euendolithic cyanobacteria occupy subtidal carbonates. In shoaling sands (ooids), mollusk shells, and shell fragments in subtropical regions of the Bahamas, and the Arabian Gulf, assemblages are dominated by a number of different cyanobacteria of the genus *Hyella* (Al-Thukair and Golubic, 1991; Al-Thukair et al., 1994) that produce boring traces of the ichnogenus *Fascichnus* (Figure 9) (Radtke and Golubic, 2005). Relatively stable carbonate substrates such as bivalve shells, coral skeletons, and carbonate hard grounds in illuminated marine waters are dominated by septate euendolithic chlorophytes, *Phaeophila* and *Eugomontia*, which produce traces of the ichnogenus *Rhopalia* (Radtke, 1991; Golubic and Radtke, 2008) and by the siphonal chlorophyte, *Ostreobium quekettii*, which produces trace *Ichnoreticulina* (Figure 3) (Radtke and Golubic, 2005). Similar assemblages of euendoliths and their traces have been studied in profiles across coral reefs in Mexico (Günther, 1990) and Jamaica (Perry, 1998).

Ostreobium reaches considerable depths in clear oligotrophic tropical seas. This endolith dominates carbonate substrates between 10 and 150 m and is still present in the rocks at 300 m (Vogel et al., 2000). The maximum

Bioerosion, Figure 8 Dense populations of the cyanobacterium *Kyrtuthrix dalmatica* Ercegovic presented in situ. Double embedded preparation renders the rock transparent (lower part of the picture). depth for phototrophic euendoliths is reached by the cyanobacterium *Plectonema* (*Leptolyngbya*) *terebrans*, which was identified alive at 370 m depth (Lukas, 1978). Conchocelis stages of bangialean rhodophytes penetrate carbonate substrates to a depth of 78 m in the North Sea (Clokie et al., 1981). The actual depth of occurrence of all phototrophic euendolithic organisms depends on light penetration in the waters which can be affected by environmental factors such as terrigenous inputs of nutrients and sediments, and eutrophication in general. Depth zones have, therefore been defined by Glaub et al. (2001) in relative terms as: “shallow euphotic zone,” divided in three stages to cover the supratidal, intertidal, and shallow subtidal ranges, “deep euphotic zone,” “disphotic zone” (defined by light penetration between 1% and 0.001% of the incoming illumination at the surface), and “aphotic zone” beneath that.

Euendolithic fungi penetrate carbonate substrates that contain organic matter. They permeate carbonate substrates with their thin, branched hyphae (Figure 4) (Mao-Che et al., 1996). Fungi also parasitize on euendolithic algae (Bentis et al., 2000; Priess et al., 2000; Golubic et al., 2005) and form lichens with cyanobacteria (Le Campion-Alsumard and Golubic, 1985) and some chlorophytes (Golubic and Schneider, 2003). Euendolithic organotrophs such as bacteria and fungi may occur at any depth, including abyssal ranges (Golubic et al., 1984; Golubic et al., 2005). Their traces have been described in deep-water coral reefs (Wisshak, 2006).

Phototrophic euendoliths in corals

Distribution of phototrophic euendoliths deep into the disphotic zone of the oceans is paralleled by the depth of their penetration into carbonate substrates. *Plectonema*

terebrans and *Ostreobium quekettii* penetrate over 1 mm deep into live and dead coral skeletons (Tribollet, 2008a). These euendolithic phototrophs can survive and grow at light intensities as low as 0.04% of the surface illumination and are, therefore, considered oligophotic (Fork and Larkum, 1989; Shashar and Stambler, 1992; Schlichter et al., 1997). The ability to harvest energy by extending the window of photosynthetically useful radiation is facilitated in cyanobacteria by the auxiliary phycobilin pigments, including optional chromatic adaptation in some taxa. Different strategies are employed by *Ostreobium*. This green alga can increase the proportion of Chlorophyll-b (Schlichter et al., 1997), or use light from the long-wave portion of the solar spectrum (Koehne et al., 1999; Wilhelm and Jakob, 2006).

The ecological niche that euendolithic algae occupy in the carbonate skeletons of live calcifying organisms such as growing corals requires a positive phototropic growth orientation and a rate of growth and carbonate penetration that keeps up with the host's accretion rates. This condition is fulfilled by *Plectonema terebrans* and *Ostreobium quekettii* (Figure 10), and less frequently by Conchocelis stages in the life cycle of bangialean rhodophytes. *Ostreobium quekettii* is omnipresent in live corals (Lukas, 1973, 1974) as euendolith and as cryptoendolith (Schroeder, 1972) (Figure 11).

The distribution and abundance of *Ostreobium* in live corals and its possible interactions with the coral host has been the subject of several studies, leading to the

Bioerosion, Figure 9 Resin replicas of cyanobacterial borings in an ooid sand grain, Joultar's Key, Andros Island, Bahamas. The boring patterns are ichnospecies *Fascichnus frutex* produced by colonies of the coccoid cyanobacterium *Hyella gigas*. Scale bar is 50 μ m long.

suggestion of a symbiotic relationship. This proposal was supported by documenting an exchange of nutrients and metabolic products between the two partners living in close proximity (Shashar and Stambler, 1992; Schlichter et al., 1997). Chemistry of pore waters in corals was reviewed briefly by Risk and Muller (1983). Such an ectosymbiotic relationship between euendoliths and live coral polyps may help the survival and recovery of the latter following the stress of coral bleaching events (Fine et al., 2006). *Ostreobium* responds to coral bleaching first by photoinhibition, followed by rapid accommodation to higher light intensities. This response leads to an increase in growth, identified as a bloom of *Ostreobium* (Fine et al., 2006). Uneven density of *Ostreobium* filaments and their pigmentation in coral skeletons is expressed as green bands (Lukas, 1973), which were interpreted as periodic blooms of the alga (Highsmith, 1981). Le Campion-Alsumard et al. (1995a) showed that euendolithic algae in coral skeletons tend to increase in density beneath the polyp layer whenever coral growth slows down (Figure 12). It is, therefore, conceivable that the green bands studied by Lukas and illustrated by Le Campion-Alsumard et al. (1995a, Fig. 7) represent a record of past coral bleaching events.

Organotrophic euendoliths in corals

Regular inhabitants of coral skeletons other than phototrophs are euendolithic fungi. Their penetration depends on the distribution of organic matter in the bored substrate, including that which was contributed by euendolithic phototrophs. It has also been documented that fungi attack euendolithic algae in coral skeleton as well as the live coral polyps (Priess et al., 2000; Benthis et al., 2000). To protect itself, the coral responds by initiating deposition of a dense carbonate layer over the fungal

Bioerosion, Figure 12 A head of a hermatypic coral *Porites lutea* cut open to reveal perforations by a green zone of phototrophic microborer *Ostreobium quekettii*, underneath the polyps, and deeper inside the skeleton a macroborer, *Cliona* sp., which undermines the coral base. Lee Stocking Island, Bahamas.

borehole. As the fungus continues to penetrate, such deposits tend to accumulate, building conical structures reminiscent of deposition of pearls around foreign bodies by oysters (Le Campion-Alsumard et al., 1995b). The reported interrelations between fungi and corals (Priess et al., 2000; Benthis et al., 2000) have been recently complemented experimentally by demonstrating stimulation of cultured coral skeletogenic cells by the basidiomycete fungus *Cryptococcus*, independently isolated from a coral skeleton (Domart-Coulon et al., 2004). Several strains of ascomycete fungi were isolated earlier from corals in conjunction with the study of their parasitic role (Kendrick et al., 1982).

Boring foraminifera

Carbonate penetration by benthic foraminifera is a widespread but little known activity. Some euendolithic foraminifera construct their tests inside their boreholes (Cherchi and Schroeder, 1991), but more often, only boring traces of soft-bodied parts remain inside carbonate substrate, leaving only spine-like traces of their pseudopodia. Foraminifera include taxa that are strictly organotrophic as well as those that contain phototrophic endosymbionts (*Symbiodinium*, zooxanthellae). The latter group is expected to be limited in distribution to illuminated parts of the ocean, but their relation to microboring activity is not known. Boring traces of foraminifera overlap in size the ranges usually assigned to micro- or macroendoliths. Most of them are small, possibly temporary anchoring devices. Boring foraminifera include also large forms (Rosalinidae) that parasitize on mollusks by perforating their shells (Smyth, 1988; Cedhagen, 1994). The mollusk responds to the attack in a way similar to coral's defense from predatory fungi by producing layers

Bioerosion, Figure 13 Predatory foraminifer *Rosalina* sp. attacking a mussel. The protist has perforated the shell as well as layer by layer of the nacreous pearl-like cone that the mollusk has produced in defense. Polished and lightly etched petrographic section. SEM of the MCZ, Harvard University.

of nacre over the area of penetration (Figure 13) (reviewed by Beuck et al., 2008).

The naming of boring foraminifera became a subject of controversy when the organism described as *Globodendrina*, on the basis of the interpretation of its fossil trace (Plewes et al., 1993), was subsequently formally described as the trace *Semidendrina* (Bromley et al., 2007).

Distribution of macroborers

Marine macroborers are mostly filter-feeders, and thus need to maintain contact with the substrate surface in order to access food from the surrounding water column. Accordingly, these internal bioeroders tend to thrive in eutrophic coastal waters (Risk et al., 1995), and are less abundant in the offshore oligotrophic settings (Tribollet and Golubic, 2005), with particularly strong offshore decline recorded for the abundance of boring bivalves (Sammarco and Risk, 1990).

Depth distribution of macroboring organisms has not been assessed as vigorously as for microboring organisms. The boring sponges seem to show an increase in abundance with depth within the range between 10 and 30 m (Zundelevich et al., 2007). Most work on macroboring organisms concentrates on shallow marine habitats and reefs (Mariani et al., 2000). Macroboring traces, however, have been also observed in deep-sea corals and shells (Freiwald et al., 1997; Wisshak, 2006).

Depth of penetration of macroborers into substrates varies, depending on the organism and its size. Small polychaetes, larvae, and juveniles do not penetrate deep inside substrates, and the depth of penetration and volume of the substrate excavated increase with age of the macroborer (Figure 6). Some macroborers are nearly

microscopic in size. The zooetia of boring bryozoa, for example, are connected by stolones that bore tunnels close in dimensions to those of endolithic algae and to borings of microbial heterotrophs described as *Orthogonum* (Radtke, 1991). Larger euendoliths include cirriped crustaceans and various boring worms, such as polychaetes, phoronids, and sipunculids. These borers remove relatively small amounts of substrate due to their small size when their population density is low. In higher concentrations, they are known to effectively damage mollusk shells (Bergman et al., 1982).

Interaction between macroendoliths and their coral hosts has produced distinctive patterns and taphonomic alterations (Scoffin and Bradshaw, 2000), analogous to distinction between live and dead corals shown for microbial euendoliths. The exceptionally pervasive macroborers are clionids (Mariani et al., 2000), which produce extensive branched and interconnected systems of galleries within carbonate substrates (Figure 5) while communicating with the surface by numerous small openings; other boring sponges are partially endolithic with bodies that overgrow the substrate as well as penetrate inside (Rützler, 2002). Clionid sponges are known to attack the substrate at the cellular level by carving out silt-to sand-sized chips that are then expelled into the environment contributing to formation of fine-grained sediments (Pomponi, 1980). However, the chemical dissolution that accompanies this process removes more than three times the amount of carbonate than is removed by the mechanical chip removal (Zundelevich et al., 2007). Traces of sponge borings are known by the name of *Entobia* (Bromley and D'Alessandro, 1989), which are characterized by species-specific boring patterns. Like microborers and sponges, other macroborers, such as bryozoans, cirripeds, and bivalves excavate spaces that comply closely with the outlines of their bodies (e.g., Hutchings, 1986; Scott and Risk, 1988). All these macroboring organisms preserve well in the fossil record and provide useful information for paleoecological research.

Bioerosion over geological time

Commonly asked questions about the euendolithic mode of life are: Why do they bore? When and how did this habit evolve, and which selective pressures supported that habit. An early hypothesis that microbial euendoliths evolved seeking shelter to escape the grazing metazoans when those evolved around 540 million years ago, was rejected since Proterozoic euendoliths were discovered in much older strata (Campbell, 1982). Entire assemblages of fossil euendolithic cyanobacteria have subsequently been discovered in Neoproterozoic silicified ooids (Knoll et al., 1986). The oldest microbial euendoliths were found to bore ancient stromatolites in over 1,500 Myrs. old rocks (Zhang and Golubic, 1987).

The observation that many euendoliths enter the substrate via a small opening, from which they expand laterally, i.e., parallel to the surface, suggests that they

successfully avoid competition with epiliths for settlement ground. The phototrophic euendoliths evolved efficient light-harvesting systems to operate at low light levels exploiting different spectral ranges. This adaptation is important because the light available to euendoliths changes qualitatively and quantitatively as it is filtered by the water column, mineral substrate, coral endosymbionts, and/or epilithic turf and crusts (Fork and Larkum, 1989; Schlichter et al., 1997; Koehne et al., 1999).

The evolution of invertebrates with mineralized skeletons in the course of the early Phanerozoic provided microbial euendoliths with new substrates. Euendoliths have occupied these substrates successfully, leaving a wealth of microboring traces throughout the Phanerozoic (Glaub and Vogel, 2004; Glaub et al., 2007). Organically preserved euendolithic rhodophytes were found occupying crinoid ossicles in rocks of Upper Silurian age (Kazmierczak and Golubic, 1976). They were identified and described as *Palaeoconchocelis starmachii* (Campbell, 1980). Many microborings remained preserved as natural casts due to differential solubility of borehole fill versus bored matrix (e.g., Harris et al., 1979); however, surprisingly high number of boreholes remained empty, so that they have been successfully cast by polymerizing resins and observed by scanning electron microscopy (Golubic et al., 1970). This finding illustrates the role of microborers in contributing to the microporosity of rocks, which serve as petroleum reservoirs (Cantrell and Hagerty, 1999).

Early diversification of microboring organisms, which was initiated during Proterozoic, continued throughout the Phanerozoic. In Middle Cambrian, both body and trace fossils of microbial endoliths were present (Stockfors and Peel, 2005), and entire microboring assemblages appear to

be well-established by the Ordovician times (Figure 14), with about 35% of fossil taxa that survived to the present; this record also includes the first occurrence of borings attributable to euendolithic green alga *Ostreobium* and chytrid fungi (Glaub and Vogel, 2004). In general, microboring traces constitute attractive markers for identification of paleoenvironments (bio- and litho-facies), but are less reliable as stratigraphic markers. Although microborers in their protected niches persisted through periods of major extinction, they seem to show bursts of diversification at the base of the Mesozoic and Cenozoic eras (Glaub and Vogel, 2004).

Evidence of predatory macroboring has been found in late Proterozoic strata associated with the evolution of the earliest exoskeletal organisms (Bengtson and Zhao, 1992). The diversification of macroboring organisms proceeded during the early Paleozoic when representatives of most animal phyla appeared in the fossil record (Palmer and Plewes, 1993; Wilson, 2007). The sheltered habitat that macroendoliths occupy does offer an advantage and protection from predators and may have been a strategy favored by the early selective pressure. An overview of the evolutionary history of macroborers is provided by Taylor and Wilson (2003), and the use of macroborers in stratigraphy is discussed by Bromley (2004). Boring traces of sponges and worms (e.g., *Tripanites*) were observed from the Cambrian on. Macroborers diversified thereafter and became well-established by early Ordovician times (Ekdale and Bromley, 2001) when ctenostome boring bryozoans also occurred for the first time in addition to boring sponges and worms (Mayoral, 1991). Small stellate *Dendrina*-type borings diversified in Devonian (Vogel et al., 1987) and later in the Cretaceous (Hofmann, 1996). These are now attributed to boring foraminifera (Bromley et al., 2007).

Bioerosion, Figure 14 Resin replicas of borings in late Ordovician brachiopod *Raphinesquiana alternata* from the shallow marine facies of Tanner Formation, Richmond Group, southeastern Indiana, USA. Two out of four boring morphotypes produced by phototrophic euendoliths include: coccoid cyanobacteria (left) and filamentous algae with changing diameter, a possible chlorophytes. Scale bar is 100 μ m long. (From Golubic, S., Knoll, A. H., and Rann, W., 1980. Morphometry of late Ordovician microbial borings, American Association of Petroleum Geologists, Bulletin, 64, 713.)

The first borings attributed to endolithic mussels appeared in the Carboniferous, whereas the first boring cirripedia were documented in Permian strata (Simonsen and Cuffey, 1980). Modern type macroboring communities became established during the Jurassic times (Fürsich et al., 1994).

Synergistic relations among agents of bioerosion

Phototrophic microbial euendoliths are distributed over large areas of coastal limestone, coral rubble, and other carbonate substrates in illuminated marine benthic habitats. Their growth and substrate penetration stabilize at the light level of compensation (where the rates of photosynthetic activity equal respiration). If left alone, the bioerosion by phototrophic euendoliths would remain limited to a few millimeters at the substrate surface. However, as primary producers, euendolithic cyanobacteria and algae attract and support a variety of grazing animals, which periodically remove layers of carbonate substrate together with the resident epiliths and some endoliths. This synergism between euendoliths and their grazers converts an intrinsically self-limited process into a progressive one with significant bioerosive impact (Schneider and Torunski, 1983). For example, the removal of a thin surface layer of the rock by hard, magnetite reinforced radula of a grazing gastropod (Figure 15) causes a displacement of the compensation depth for phototrophs deeper into the rock, leading to a resumption of boring. With continuing grazing, the horizon with euendoliths moves like a front through the rock. The abraded carbonate particles break along cyanobacterial perforations, as they pass through the digestive system and can be recognized in the sediment (Figure 16). The interaction between microborers and their grazers degrade coastal rocks and contribute to

Bioerosion, Figure 15 The synergistic relation between microboring phototrophs and their mollusk grazers. Penetration in the rock is limited by light penetration and stops at the depth of compensation, where respiration equals photosynthesis. As grazers remove a layer of rock the light penetrates deeper, and the boring proceeds from the old depth of compensation (ODC) to a deeper new depth level (NDC), and progresses further with each passage of the grazer. (Modified from Schneider and Torunski, 1983.)

fine-grain sediment accumulation in the environment. A different mechanism with similar results was described for macroboring clionid sponges (Schneider and Torunski, 1983).

Grazing is a normal condition on coral reefs, so that the composition, diversity, and integrity of primary producers, which coevolved with the grazers, also depend on them. The rates of grazing and microbioerosion by euendoliths are positively correlated (Tribollet and Golubic, 2005). Moderate rates of grazing appear to have a regulatory effect by promoting high productivity-to-biomass ratio among the epilithic and endolithic cyanobacteria and algae (Vooren, 1981). In addition, moderate grazing provides new settling grounds for endoliths and coral larvae (Sammarco, 1980). The zone of active microbioerosion at any time contains only the “residual standing crop” of microborers, which does not include the microbial contribution already removed by grazers. These dynamic relations need to be taken into account when rates of bioerosion are calculated and attributed to different components of the system (Chazottes et al., 1995; Tribollet and Golubic, 2005).

Without grazing, the reefs would be overgrown by soft-bodied algae, as it is achieved locally by aggressive territorial damselfish that deter sea urchins and other grazing fish. Damselfishes are known to maintain and weed algal

Bioerosion, Figure 16 Dense distribution of euendolithic cyanobacterial boreholes outlines a pattern, which determines the fragmentation of rock upon being grazed and passed through gastropod's digestive tract. These fragments were recognized in the sediment based on margins scalloped by boreholes, reminiscent of perforations that facilitate separation of postal stamps. Scale bar is 50 μ m long. (Modified from Torunski, H., 1979. Biological erosion and its significance for the morphogenesis of limestone coasts and for nearshore sedimentation (northern Adriatic). (Senckenbergiana maritima, 11: 193–265.)

farms, thus influencing macrobioeroding communities in the process (Sammarco et al., 1987). The results of grazer-exclusion experiments (Wanders, 1977), which showed a successional shift in species composition in favor of macroalgae and in a loss of some normally abundant and structurally important species of coralline algae, confirmed independently the experimentation performed by damselfish.

In contrast, excessive grazing is expected to be self-limiting and thus cyclical. When grazing pressure is too intense, as in the case of populations of grazing urchins studied on la Reunion Island, Indian Ocean (Chazottes et al., 2002), or in pollution impacted Faa reef at the airport of Papeete (French Polynesia; Pari et al., 1998), grazing and microbioerosion become negatively correlated (Figure 17). When grazing is too intense, euendoliths may be completely removed, thus reducing grazing while new euendoliths recolonize the barren grounds.

The optimal conditions for the interaction between euendoliths and their grazers are exemplified by the formation of intertidal bioerosional notch (Neumann, 1966) (Figure 18). Tidal ranges on rocky coasts represent an ecotone environment, a transitional zone between ecosystems that are adapted either to marine or to terrestrial environments. This transitional zone may be perceived as extreme for both. It is characterized by a gradient of variable water supply, solar irradiation, and salinity. Organisms along that gradient are arranged in distinct zones (Figure 19). Both, microbial euendoliths and their grazers optimize their activity in dependence on local water supply. Their activity, in turn, improves local water retention. The upper tidal ranges are harsh environments dominated by euendolithic cyanobacteria, often by a single species. Accordingly, the rates of bioerosion are modest. In contrast, the lower ranges with regular water supply by tides are more diversified, inviting competing microboring

and grazing taxa. The coastal profile reflects the resulting bioerosion like a diagram, with the location of the notch corresponding to maximum bioerosion. The pattern of bioerosional notch formation is repeated around the margins of flat-bottom intertidal and supratidal rockpools although the species composition of the euendolith and grazer populations of the pools may be distinct from those of the large-scale coastal notches (Radtke et al., 1996).

In the supratidal ranges, the distribution of wave spray, water retention, and solar irradiation selects and controls the combined boring and grazing activity of darkly pigmented euendolithic cyanobacteria and small grazing gastropods. Consequently, the coastal limestone rocks are biodegraded selectively, a process that enhances the relief of the coastal rock surface, leading to formation of elaborate sharp-edged rock forms called biokarst (Figure 20). The term emphasizes the biological modification of the limestone dissolution forms that are characteristic of world's karstic regions (Schneider and Torunski, 1983).

Macroborers are orders of magnitude larger than microborers (compare Figures 6 and 7) and can excavate significantly larger volumes of carbonate than microbial euendoliths but, unlike the microborers, the macroborers are not subjected to grazing pressure. Macroborers self-stabilize once they reach their adult size and thus are not part of the advancing bioerosion. Macroboring activity may lighten the reef structure but does not necessarily imperil the structural integrity of the reef's framework (Scott and Risk, 1988); although, excessive damage to corals by macroborers makes them vulnerable to physical forces, usually associated with the passage of tropical storms (Clark and Morton, 1999). Macroboring increases porosity of rocks and promotes formation of new settling grounds and additional ecological niches, an activity that can be viewed as a positive contribution to the reef ecosystem.

Bioerosion, Figure 17 Heavy grazing by *Echinometra mathaei* has bypassed the experimental exposure blocks and undermined their basis. Coral reef under the influence of pollution at Faa, near Papeete, French Polynesia. The blocks are about 10 cm wide. (Courtesy of M. Peyrot-Clausade.)

Bioerosion, Figure 18 Bioerosional notch on limestone coast in protected shallow lagoonal environment at Lee-Stocking Island, Bahamas.

Bioerosion, Figure 19 Bioerosional notch carved into a coastal profile by microbial euendoliths and their grazers on a small island on the Bahamas carbonate platform, near Lee Stocking Island. Zonal distribution of phototrophic microborers listed above, comprising cyanobacteria (blue), chlorophytes (green), and Conchoecelis stages of rhodophytes (red) is correlated with zonal distribution of their grazers, listed left, and with the tidal levels (ST = supratidal; HT = high tide; MT = mean tide; LT = low tide). (Modified from Radtke et al., 1996.)

Bioerosion, Figure 20 Biokarst shaping of coastal carbonate rocks caused by combined bioerosion of euendolithic cyanobacteria and small gastropods. Scale bar is 10 cm long.

Production and cementation of sediment is another process that re-enforces reef framework, and is in part facilitated by endolithic organisms. There is good evidence that some of the carbonate dissolved by microbial euendoliths is re-precipitated, thus contributing to formation of micritic encrustations in marine (Kobluk and Risk, 1977; MacIntyre et al., 2000) and freshwater

environments (Schneider et al., 1983). *Ostreobium quekettii* dissolves carbonate, which then precipitates around its filaments when the alga exits the substrate and inhabits the coral pore spaces as cryptoendolith (Figure 21). Precipitation of carbonate on filaments of *Ostreobium*, was observed first in corals (Schroeder, 1972) and later in stromatolites and live corals (Feldmann and McKenzie, 1998; Nothdurft et al., 2007).

Rates of bioerosion

Quantification of bioerosion rates includes direct observations of behavioral patterns of particular organisms such as grazers (Hoey and Bellwood, 2008) and their selective impact (Rojtan and Lewis, 2005). A different approach involves measuring grazers' carbonate consumption rates (Mokady et al., 1996). Other approaches involve assessment of long-term substrate removal from experimentally exposed carbonate blocks without (Kiene and Hutchings, 1992), or with identification of participating bioeroders (Chazottes et al., 1995, 2002; Tribollet and Golubic, 2005; Tribollet, 2008a). The latter approaches assess the total bioerosion rates (macrobioerosion + microbioerosion + grazing) by measuring changes in substrate size and density over time (Chazottes et al., 1995; Tribollet and Golubic, 2005). The techniques involve measurements of eroded areas in surface projection and in vertical sections, using light and scanning electron microscopy with

Bioerosion, Figure 21 View of the fractured skeleton of the coral *Montastrea*, invaded by *Ostreobium quekettii*. The euendolithic filaments of this chlorophyte produced the perforation in the skeleton (arrow), whereas the cryptoendolithic ones are covered by precipitate. Scale bar is 10 μm long.

image analysis. Carbonate removal rates are calculated for each dominant species of euendoliths as described by Tribollet (2008a). Variations on analytical methods are described in Chazottes et al. (1995), Kiene et al. (1995), and Vogel et al. (2000). The rates expressed in kg or $\text{mol CaCO}_3 \text{ m}^{-2}$ of total surface area of substrate exposed to bioerosion or m^{-2} of reef planar area per unit of time are recommended, but not always implemented in the literature, which makes comparisons of the results of different studies difficult.

Bioeroding organisms are ubiquitous in carbonate ecosystems and their efficiency of carbonate removal in coral reefs varies between 0.002 and $1.4 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ y}^{-1}$ (Chazottes et al., 1995; Vogel et al., 2000; Carreiro-Silva et al., 2005; Tribollet and Golubic, 2005). Dissolution of carbonate by microbial euendoliths, measured in a tropical lagoon by exposing sand-sized particles to euendolith settlement and excluding grazers by a $250 \mu\text{m}$ size nylon mesh, was estimated to be $350 \text{ g m}^{-2} \text{ y}^{-1}$ (Tudhope and Risk, 1985). These rates should vary with depth (Vogel et al., 2000), type of substrate (Perry, 1998; Zubia and Peyrot-Clausade, 2001), grazing pressure (Reaka-Kudla et al., 1996; Chazottes et al., 1995, 2002), sedimentation (Tribollet and Golubic, 2005), and eutrophication (Carreiro-Silva et al., 2005).

Tribollet and Golubic (2005) showed that carbonate dissolution by euendoliths in synergy with grazers along an inshore–offshore profile across the Great Barrier Reef was the dominant bioerosion process over time. They also quantified the combined yearly rates of grazing per 1 m^2 of exposed surface area to be between 0.04 and 1.8 kg of CaCO_3 . Macroborers as filter-feeders were important only

on inshore reefs where waters were rich in particulate matter (Risk et al., 1995). Macroborers eroded between 0.03 and $0.38 \text{ kg m}^{-2} \text{ y}^{-1}$. Combined interactive activity of grazing and microbioerosion contributes more to the total bioerosion of the reefs than macrobioerosion (Tribollet and Golubic, 2005).

Grazing rates vary depending on the organism. Rates by sea urchins are often very high. Grazing rates measured on Galapagos Islands reach up to $22 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ y}^{-1}$ (Reaka-Kudla et al., 1996). Mokady et al. (1996) measured consumption of grazing echinoids in the Red Sea. They observed that a meal of a sea urchin contained on the average three times more carbonate per weight than organic food. According to their calculations, removal of carbonate by a single sea urchin could reach $1 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ y}^{-1}$, depending on the size of the animal. The actual removal per area then depends on grazer population densities, which are commonly reciprocal to the average size of the animal. Grazing by extremely dense populations of small gastropods has been studied in the intertidal ranges (Schneider and Torunski, 1983), but has largely been ignored in the coastal subtidal ranges and on the reefs where there are also large numbers of small gastropods.

Summary: bioerosion and the carbonate budget of coral reefs

A carbonate ecosystem with a positive carbonate budget occurs when carbonate production, due to growth of calcifying organisms and precipitation of CaCO_3 , is higher than carbonate dissolution and/or exportation of carbonate sediments to the open ocean (e.g., Le Campion-Alsumard et al., 1993). An unbalanced carbonate budget in favor of destructive forces can be observed in coral reef ecosystems, which are mostly made of carbonates (Peyrot-Clausade et al., 1995; Reaka-Kudla et al., 1996; Pari et al., 1998). Such a disequilibrium between reef constructive forces (production of carbonates) and reef destructive forces (mainly bioerosion) can lead to physical losses of reef framework and consequently to a loss of reef diversity (Hallock, 2005; Wilkinson, 2004).

The balance between constructive and destructive forces is critical for coral reefs, particularly in view of global warming and the expected rise in sea level. It is predicted that the rising atmospheric pCO_2 due to human activities and the consequent ocean acidification (Tribollet et al., 2006), in conjunction with the rising seawater surface temperature, overfishing, and eutrophication (Szmant, 2002), will increase the rate of coral morbidity and mortality (Mumby et al., 2001; Hallock, 2005). This may lead to a shift from coral-dominated to algal-dominated reefs, with a loss of corals as one of the main frame-builders in the reefs (Szmant, 2002; Hallock, 2005). Although the effects of the above combined factors on bioerosion processes are poorly known, the integrity of coral reefs is increasingly in jeopardy (Hoegh-Guldberg, 1999; Wilkinson, 2004; Kleypas et al., 2006).

Coral reefs protect tropical coastlines and oceanic islands (Spencer and Viles, 2002). In the past they were able to grow and keep up with changes in seawater level. In order to better monitor and to preserve coral reefs it is essential to quantify carbonate budgets accurately. Different techniques have been used to achieve this goal, including alkalinity method of seawater passing over the reefs, which measure both constructive and destructive effects simultaneously. The alkalinity method provides an instantaneous measurement of reef net calcification rate ($\text{kg CaCO}_3 \text{ m}^{-2}$ of planar reef area d^{-1}). This provides a fast estimate of whether the reef is accreting or dissolving (Gattuso et al., 1999; Langdon et al., 2000). However, this method does not show which organisms are responsible for carbonate production, and which for bioerosion, nor does it predict the reef's carbonate budget over time. Additional techniques were introduced, which include monitoring of chemical and biological variables such as coral cover, coral recruitment and settlement, coral growth and calcification rates, and rates of macrobioerosion (Edinger et al., 2000). These studies have shown that inshore reefs, disturbed by sedimentation and eutrophication, had a negative carbonate budget, even without considering microbioerosion and grazing rates. However, budget calculations of "pristine coral reefs" according to the same study (Edinger et al., 2000) have to be considered with caution, because grazing and microbioerosion were not quantified, and these processes are often greater in "pristine" oligotrophic reefs than at the "disturbed" inshore reefs (Tribollet and Golubic, 2005). The studies of carbonate budget in reefs stress the importance of simultaneous analyzes of constructive and destructive forces over time and under changing environmental conditions if the state of health of coral reefs, and more generally of carbonate coastal ecosystems, has to be maintained and improved.

BIOFILMS

Joachim Reitner

University of Göttingen, Göttingen, Germany

Definition

Nearly all hard surfaces exhibit biofilms, organic coatings of microbial cells which are enclosed in extracellular polymeric substances (EPS). Biofilms interact between hard substrates such as minerals and rocks, water bodies, and the atmosphere. Metabolic exchange processes controlled by biofilms, globally influence bio-geochemical cycles.

Biofilms and microbial mats are benthic systems formed by different microbial communities which secrete hydrated mucus substances (EPS) (e.g., Characklis and Wilderer, 1989; Costerton et al., 1987, 1995) in various amounts. These EPS substances are mainly polysaccharides, glycoproteins, exoenzymes, and nucleic acids (Sutherland, 1977; Decho, 1990; Wingender et al., 1999). Biofilms and microbial mats display a continuous spectrum ranging from thin micrometer-sized coatings of mono-specific and poly-specific microbial populations up to centimeter thick communities of various microbes such as archaea, bacteria, eukaryotic algae, fungi, and protozoa. In many cases, these thick microbial mats exhibit a clearly visible ecological zoning owing to the presence of different microbial communities which are often characterized by colored pigments. The geobiological importance of microbial mats was recognized early by geoscientists (Walcott, 1914; Black, 1933; Pia, 1933) in contrast to the hardly visible biofilms which are globally much more widespread. Engineers and microbiologists, for example, Characklis and Wilderer (1989); Flemming (1991); Muyzer et al. (1993); Costerton et al. (1987), (1995); Neu and Lawrence (1999), have recognized the enormous importance and potential of biofilms in

Biofilms, Figure 1 Cyanobacterial biofilm forming a modern aragonitic stromatolite (Walker Lake, Nevada). Biofilm is dominated by filamentous cyanobacteria – *Calothrix* (C). Few coccoid cyanobacteria are also present (CC). Within the youngest lithified part, remains of cyanobacterial sheets are visible (LS).

many common processes. Geoscientists have increasingly investigated the rock- and mineral-forming potentials of biofilms in the 90s of the last century (e.g., Ferris, 1991; Pedley, 1992; Reitner, 1993). Biofilms were also found in deep subsurface environments and, significantly for the Deep Biosphere, up to the upper known temperature limit of life (110–120°C) (Pedersen, 1993; Fyfe, 1996; Gold, 1999; Stetter, 1994, 1996).

Organo-films are special organic coatings which are formed by various macromolecules and do not contain living cells. Organo-films are taphonomic remains of biofilms or newly formed from biogenic degradation products (geopolymers sensu Killops and Killops, 1997; Gold, 1999). Adsorption on mineral surfaces and self organizing catalytic processes play a central role during formation (Ferris et al., 1996; Reitner, 1993).

Stromatolites, thrombolites, and generally microbialites, are lithified products of bio- and organofilms, as well as thick microbial mats (Figure 1).

BIOFILMS AND FOSSILIZATION

Joachim Reitner

University of Göttingen, Göttingen, Germany

Synonyms

Carbonaceous bacterial biofilms; Hautschatten

Definition

Microbial biofilms cover normally in aquatic environments dead organisms and control partly the process of decay. The soft tissues of the body outline are preserved as a layered structure which comprises a carbonaceous microbial biofilm, in the literature often called “Hautschatten” (Figure 1). Fossils with soft part preservation are extremely rare, but under certain circumstances, like suboxic or anaerobic conditions, remains of their soft tissues with detailed histological fabrics are found. The evidence of non-biomineralized soft tissue normally degrading completely during decay is linked with special microbial processes. This exceptional preservation requires soft tissues to be replicated by authigenic minerals or pseudomorphed by bacterial biofilms (e.g., Wuttke, 1983; Toporski et al., 2002; Briggs, 2003). The different organs in many cases often exhibit different microbially controlled lithified biofilms with an unusual preservation of involved microbes.

Geobiological implications and examples

Understanding the relationship between decay and mineralization is of fundamental importance to palaeontologists

interested in the record of soft-bodied organisms. Soft-bodied fossils also provide insights into early diagenetic processes in sediments and give basic information on related organic geochemistry. The lack of biomineralized hard parts in many organisms is the normal condition in the fossil record. However, the mode of soft-tissue decay is far from uniform and the sum of various processes results in a preservation in so-called Konservat-Lagerstätten (Seilacher, 1970; Seilacher et al., 1985).

Derek Briggs and his group have made fundamental experiments on how the preservation of soft-tissues works (e.g., Briggs, 1999, 2003; Briggs and Kear, 1993; Briggs and Wilby, 1996; Grimes et al., 2001; Gupta et al., 2006). For example, they could demonstrate that initial pyritization of a plant tissue can be an extremely rapid process (within 80 days) and is driven by anaerobic bacterially mediated decay. They have made comparable experiments mainly with arthropods. Toporski's and coworkers' (Toporski et al., 2002) investigation on the Oligocene Enspel Maar black shale is a milestone in the research on soft-tissue preservation via microbial biofilms. The multitask biogeochemical analyses give the deepest insight into the taphonomy of soft tissue and microbial-related decay processes. The most famous locality with preserved soft tissues is the Eocene Messel locality. From this locality, soft tissues covered with lithified biofilms were first described by Wuttke (1983). Thick microbial biofilms are generally much darker than the surrounding black-shale and form the so-called “Hautschatten” and were for a long time believed to represent fossilized soft tissues. The biofilms trace back the decaying soft tissue in an anaerobic environment and “casting” of the former soft tissues. Often the digestive

Biofilms and Fossilization, Figure 1 A very well-preserved mouse (*Apodemus atavus*) from the late Pliocene fossil lagerstaette Willershausen (Lower Saxony, Germany) with perfectly preserved biofilm-related “Hautschatten” with visible remains of the former fur (Geoscience Museum University of Göttingen).

system of large fossils is excellently preserved (Franzen, 1994). Fundamental studies on biofilm soft-tissue relationship were carried out by Richter (1994) and Liebig (1997). Another intriguing example is the “soft-tissue” preservation in dinosaur bones (Kaye et al., 2008). Kaye and coworkers have found microbially altered soft tissue in a dinosaur bone and they give a critical explanation of this fact. Within their paper they discuss the processes of tissue preservation and also demonstrate the importance of recent microbial biofilm invasion and late diagenetic alteration of primarily formed pyrite framboids. The clou of this investigation is also that there is no real soft-tissue preservation – however, preserved biofilms cast the former tissue and give an idea about the original structures.

All “Hautschatten” soft-tissue preservations are probably preserved lithified biofilms and not real soft tissues.

Conclusion

Biofilms play a significant role in suboxic and anaerobic milieus preserving soft tissue remains. The body outline of dead organisms is exactly traced by the margins of the mineralised biofilms and give a perfect image of the entire fossil. These structures are often called after the German word “Hautschatten”-perservation and is commonly found under black shale condition.

BIOGEOCHEMICAL CYCLES

A biogeochemical cycle defines the pathways by which chemical elements occurring in organisms are cycled between different living and nonliving compartments on the Earth (e.g., biosphere, atmosphere, hydrosphere, geosphere, etc.). Typical driving forces of a biogeochemical cycle are the metabolisms of living organisms, geological processes, or chemical reactions. For specific reading on major biogeochemical cycles, please refer to “[Carbon Cycle](#),” “[Nitrogen](#),” “[Sulfur Cycle](#),” “[Phosphorus](#),” “[Phosphorites](#).”

BIOLOGICAL CONTROL ON DIAGENESIS: INFLUENCE OF BACTERIA AND RELEVANCE TO OCEAN ACIDIFICATION

Fred T. Mackenzie¹, Andreas J. Andersson²

¹University of Hawaii, Honolulu, HI, USA

²Bermuda Institute of Ocean Sciences, Ferry Reach, St. George's, Bermuda

Introduction

Soon after carbonate mineral particles are deposited, a series of chemical, physical, and biological processes start that can significantly alter their mineralogy, isotopic composition and chemistry, and the fabric of the accumulating sediment. These processes include dissolution and precipitation reactions, abrasion, and transport, and

ingestion and boring by organisms. The processes occurring after deposition fall into the category of diagenesis. In particular, carbonate sediments consisting of the minerals low (<4 mol% MgCO_3) and high (>4 mol% MgCO_3) biogenic and inorganic magnesian calcite and aragonite and organic matter deposited in shallow waters are repeatedly deposited, resuspended, and then deposited again during periods of elevated turbulence, which are common especially during storms. Consequently, carbonate minerals may be subjected to several depositional environments before being permanently buried in a sediment. The study of carbonate diagenesis is further complicated by the fact that significant amounts of shallow-water carbonates are commonly associated with reefs, for which traditional models of sediment diagenesis are not always appropriate.

Soon after deposition, chemical and physical changes occur in carbonate sediments as a result of a myriad of diagenetic processes. Among the most important are dissolution-precipitation reactions and major alterations of pore water chemistry by bacterially mediated oxidation of organic matter. These changes generally occur most rapidly in the upper few to tens of centimeters of sediment. It is this topic that is most fully addressed in this article. In addition, transport within the sediment of both solid and dissolved components is also of fundamental importance in diagenesis. It can be caused by physical stirring resulting from the movement of infaunal organisms (e.g., worms, bivalves, shrimp), and is called bioturbation. Closely associated with bioturbation is bioirrigation, which is a result of organisms pumping water through their burrows. Deeper within the sediment and thus later in its history, advection of pore water and molecular diffusion in pore water are generally the dominant transport processes.

The diagenetic equation

Since the early 1960s, considerable effort has gone into modeling the diagenesis of sediments. A central theme of most models is that diagenetic change results from the sum of transport and chemical and biological reactions of various types. Diagenetic models can be divided into those assuming constant conditions (steady-state models) and those taking into account factors that may vary with time (e.g., temperature, salinity, material input rates, water depth). The primary idea in the steady-state models is that a property in the sediment, at a given depth below the sediment-water interface, is time-independent (Figure 1). Thus, if one were to measure the pore water acidity (pH) in a sediment at 20 cm depth and come back 10 years later and again measure the pH at the 20 cm depth, it would be the same. This statement would be true even though the sediment was not physically the same at the 20 cm depth because of deposition during the intervening 10 years.

The general diagenetic equation from which many important models have been derived (e.g., Berner, 1980) is:

Biological Control on Diagenesis: Influence of Bacteria and Relevance to Ocean Acidification, Figure 1 Diagram illustrating under steady-state (constant) conditions how a property such as hydrogen ion concentration varies with depth as the sediment column accumulates. Note that a property at fixed depth x_1 does not change in magnitude as the sediment accumulates.

$$(\partial C_i / \partial t)_x = -\partial F_i / \partial x + \sum R_i \quad (1)$$

where C_i = concentration of solid or liquid component i in mass per unit volume of total sediments (solids plus pore water); F_i = flux of component i in terms of mass per unit area of total sediment per unit time; and R_i = rate of each diagenetic chemical, biochemical, and radiogenic reaction affecting i in terms of mass per unit volume of total sediment per unit time. An example of application of this equation would be the change in hydrogen ion concentration (pH) with time at a given depth in a sediment due to diffusive transport and the dissolution of calcium carbonate in the sediment. For a steady-state condition, Equation 1 is set equal to 0, because at a given depth x , the hydrogen ion concentration does not change with time. Steady-state models are generally more amenable to a mathematical solution than non-steady-state models. However, diagenesis in many shallow-water carbonate sediments is significantly influenced or even dominated by non-steady-state processes.

Dissolution of carbonates

Continental shelves and slopes comprise about 20% of the Earth's surface, and contain more than half of the sediments in the ocean. Recent estimates of marine carbonate burial rates indicate that between 35% and 70% of Holocene carbonate deposition has taken place on continental shelves and today's production of shallow-water biogenic carbonate ("calcareous") skeletons and tests represents about 28% of the total carbonate produced in the world's oceans.

A substantial fraction (>50%) of shallow-water produced CaCO_3 is at present time permanently buried in the sediments. In contrast, most of the CaCO_3 produced in the open ocean mainly by planktonic organisms such as coccolithophorids, forams, and pteropods dissolves before it reaches the ocean floor. As much as 50–90% of the material may dissolve in the upper 1,000 m owing to microbial decomposition of organic matter creating microenvironments corrosive to CaCO_3 particles. Typical examples of such environments include inside the guts of zooplankton or within aggregates of CaCO_3 and organic material referred to as “marine snow.” Carbonate material making it past the depth of the saturation horizon, the thermodynamic equilibrium boundary between the forward and backward reactions of precipitation and dissolution, will consequently become subject to dissolution regardless of the activity of microbes and the formation of microenvironments.

Since most shallow-water environments (coastal zone, continental shelf, banks, reefs, etc.) at present time are immersed in seawater supersaturated with respect to calcite, aragonite, and most Mg-calcite phases, dissolution of sedimentary CaCO_3 minerals in these environments is completely driven by microbially mediated processes associated with oxidation of organic material in the pore water-sediment system or boring autotrophic or heterotrophic microorganisms referred to as endoliths. In the presence of oxygen, the extent of CaCO_3 dissolution is almost completely controlled by the amount and the extent of organic matter decomposed or respired, but under anoxic conditions, oxidation of organic matter accompanied by reduction of sulfate can produce radically different

results. Most studies of the impact of chemical diagenesis on the carbonate chemistry of anoxic sediments have focused primarily on the fact that sulfate (SO_4^{2-}) reduction results in the production of alkalinity (mostly dissolved bicarbonate [HCO_3^-], carbonate [CO_3^{2-}] and carbonic acid [H_2CO_3] and CO_2 chemical species), which can cause precipitation of carbonate minerals (e.g., Berner, 1971). The reduction of the sulfate is promoted by bacteria, particularly *Desulfovibrio desulfuricans*, splitting the sulfur–oxygen bond and leading to the accumulation of dissolved chemical species of reduced sulfur (mainly H_2S and HS^- ; these sulfur species may contribute to the total alkalinity of the pore waters) in the pore waters and in sediments containing iron as ferrous sulfide minerals (mainly pyrite, “fool’s gold,” FeS_2) and free solid sulfur. Although the reaction is complex, this process can be schematically represented, using the average composition of organic matter of phytoplankton as substrate material, as:

which results in the commonly observed decrease in sulfate ion, and pH (measure of hydrogen ion concentration, H^+), and increase in total alkalinity, hydrogen sulfide (H_2S), phosphate (PO_4^{3-}), ammonia (NH_3), and total dissolved inorganic carbon (DIC) in sediment pore waters with increasing depth below the sediment–water interface.

During the early stages of sulfate reduction (~2 to 35%) (Figure 2), this reaction may not cause precipitation,

Biological Control on Diagenesis: Influence of Bacteria and Relevance to Ocean Acidification, Figure 2 The saturation state with respect to aragonite (Ω aragonite) of marine pore waters as a function of the amount of sulfate reduced to sulfide based on the model of Ben Yakoov (a). Saturation state with respect to calcite (Ω calcite) as a function of depth as observed in Mangrove Lake, Bermuda sediment pore waters. (From Morse and Mackenzie, 1990.)

but rather results in undersaturation conditions with respect to carbonate minerals because the impact of lowered pH (increasing H^+) has a larger negative effect on the total alkalinity than the positive effect on this chemical property arising from reduction of sulfate. Carbonate ion activity decreases rapidly as it is "titrated" by CO_2 from organic matter decomposition abetted by bacteria leading to a decrease in pore water saturation state. This process is evident in observational data for Fe-poor shallow water carbonate sediments from the Bahamas and has been confirmed in recent studies of sediments from Florida Bay, in the Checker Reef of Kaneohe Bay, Oahu, Hawaii, and in organic-rich sediments of Mangrove Lake, Bermuda (Morse and Mackenzie, 1990) and elsewhere. In Mangrove Lake, it was shown based on model calculations that the degree of undersaturation of anoxic pore waters with respect to carbonate mineral compositions can depend significantly on the carbon to nitrogen ratio (C/N) of the labile organic matter undergoing bacterial oxidation in the sediment pore water (Figure 3).

This sulfate reduction reaction in anoxic carbonate sediments has potential importance for carbonate dissolution in shallow-water, marine environments, but its global significance remains a question. An observation of interest is that even complete sulfate reduction can return the saturation state of the pore water only to about half of its original value. Thus, the sulfate reduction reaction by itself may not promote carbonate precipitation as total alkalinity increases and partial sulfate reduction may result in carbonate dissolution. The combination of the sulfate reduction reaction and reactions primarily with iron and

manganese oxide minerals in the sediments can lead to significant calcium carbonate precipitation. This type of net process can be represented schematically as (where CH_2O is a simplified formula for organic matter):

Reaction 3 results in the pH of the waters, in the absence of carbonate precipitation, being buffered at higher pH values. It is, therefore, reasonable to expect that the effectiveness of sulfate reduction in producing carbonate dissolution or precipitation may depend in part on the availability of reactive iron. This conclusion has been demonstrated in a study of the pore water geochemistry of aluminosilicate and carbonate-rich sediments from Kaneohe Bay, Oahu, Hawaii. The aluminosilicate sediments contain abundant pyrite whereas the pyrite content of the carbonate sediments in the bay is low. Pore waters collected from the aluminosilicate sediments have higher pH values than those collected from the carbonate-rich sediments. This observation is a result of the pH values in the pore waters of the aluminosilicate sediments being buffered at higher values than those for carbonate sediments because of Reaction 3 (Mackenzie et al., 1981).

There are several processes that have been identified that can cause undersaturation of pore waters with respect to carbonate minerals, in addition to the previously discussed undersaturation conditions that may result during the early stages of sulfate reduction. These are early post-death microenvironments within organisms, oxidation of organic matter by processes preceding sulfate reduction, and oxidation of sulfides. In addition, both autotrophic and heterotrophic endoliths actively penetrate carbonate substrates by creating corrosive conditions with respect to these mineral phases. These processes commonly will be most important near the sediment–water interface. The most important process occurring prior to the onset of bacterial sulfate reduction is extensive organic matter degradation due to bacterially mediated oxygen reduction, a process important in both shallow-water and deep-sea carbonate sediments. The influence of benthic bacterial activity under aerobic conditions on carbonate mineral dissolution was nicely demonstrated by Moulin et al. (1985) for pore waters from sediments of the Gulf of Calvi, Corsica. Under aerobic conditions, the oxidation of organic matter may be written:

and if carbonate minerals were to dissolve because of the CO_2 produced by organic matter decomposition, then the reaction:

The overall net Reaction of 4 + 5 is:

Biological Control on Diagenesis: Influence of Bacteria and Relevance to Ocean Acidification, Figure 3 Diagram illustrating how the C/N ratio of the organic matter deposited influences the saturation state with respect to aragonite ($\log(IAP/Karag)$; 0.0 = saturation) of the pore waters of Mangrove Lake, Bermuda organic-rich sediments. The saturation state is shown as a function of the amount of dissolved inorganic carbon (DIC) added to the pore waters from the oxidation of organic matter by aerobic oxygen consumption and anaerobic sulfate reduction processes. (From Morse and Mackenzie, 1990.)

Reaction 6 is possible only if the pore waters are undersaturated with a carbonate phase, and there are no other competing reactions, like significant ammonia release from decaying organic matter, to increase pore water saturation state. **Figure 4** shows the increase in total alkalinity versus increase in total CO_2 (DIC) as observed in shallowly buried pore waters in the Gulf of Calvi *Lithothamnion* sp. algal-rich sediments and in low and high magnesian calcite- and aragonite-rich sediments from Mangrove Bay, Bermuda. The slopes of the regression lines for the relationships are close to 1. The slope indicates that **Reaction 6** most likely gives rise to the increased total alkalinity observed in these pore waters; that is, the H_2CO_3 produced by organic matter oxidation is stoichiometrically utilized in dissolution of a carbonate mineral phase in the sediment. Close inspection of the regression line for the Gulf of Calvi sediments in **Figure 4** shows that it does not pass through the origin. This is because about 0.1 mmol kg^{-1} of H_2CO_3 has been added to the pore waters from aerobic bacterial respiration prior to carbonate dissolution. This initial input of H_2CO_3 lowers the saturation state of the shallowly buried pore waters to that required for carbonate mineral dissolution. These pore water observations have been confirmed in experiments using a biological reactor,

Biological Control on Diagenesis: Influence of Bacteria and Relevance to Ocean Acidification, Figure 4 Increase in total alkalinity (ΔA_t , change in sediment pore water total alkalinity from that of overlying water column) and total DIC ($\Delta \Sigma \text{CO}_2$, change in sediment pore water total DIC from that of overlying water column) in pore waters of Gulf of Calvi, Corsica (insert, Moulin et al., 1985), and Mangrove Bay, Bermuda. Notice the slope of the lines of nearly 1 as predicted from **Reaction 6**. At zero total alkalinity the total DIC is not zero due to the addition of dissolved carbon species to the pore water column from the biological, mainly bacterial, remineralization of organic matter at very shallow depths (several centimeters) in the sediments above the depth, at which the waters become undersaturated with some magnesian calcite compositions and carbonate minerals dissolve with increasing depth.

and from solid phase mineralogical studies. High magnesian calcites are dissolved preferentially in these sediments, although the sediment contains a mixture of nearly pure calcite, aragonite, and magnesian calcites with up to 20 mol% MgCO_3 . In the Gulf sediments composed principally of the red alga *Lithothamnion* sp., this early diagenetic reaction has resulted in dissolution of 75% of the carbonate initially deposited. Furthermore, in the case of the study of Mangrove Bay, the pore waters were sampled every few hours during a complete, 24 h, diel cycle. The trend and relationship between changes in total alkalinity and total DIC are essentially the same as observed in the sediments of Gulf of Calvi. In addition, sea grasses, such as *Thalassia*, which covers vast areas of the bottom in Mangrove Bay probably enhances carbonate dissolution in these sediments by releasing oxygen through its roots and rhizomes into the sediments that consequently enhances decomposition of organic matter and production of H_2CO_3 . Evidence from the Bahamas bank has clearly demonstrated enhanced calcium carbonate dissolution owing to this process (Burdige and Zimmerman, 2002).

Other reactions of less importance than those above leading to undersaturated conditions with respect to calcium carbonate near the sediment–water interface include nitrate reduction and fermentation (e.g., Aller, 1980). Such reactions may also be important near the sediment–water interface of continental shelf and slope sediments, where bioturbation and bioirrigation can result in enhanced transport of reactants. Generally, as the water depth increases over continental slope sediments, the depths increase within the sediment at which significant sulfate reduction and reactions other than sulfate reduction influence carbonate chemistry.

Carbonate dissolution and ocean acidification

Future increases in atmospheric CO_2 owing to human activities, such as burning of fossil fuels and land-use changes, result in increased uptake of part of this CO_2 by ocean surface seawater and formation of carbonic acid. As the term implies, dissociation of carbonic acid produces hydrogen ions, which results in increasing acidity and decreasing pH of seawater and therefore the name ocean acidification. Surface seawater pH has already decreased by approximately 0.1 pH units since the onset of the Industrial Revolution and is anticipated to decrease by another 0.2–0.3 pH units by the end of the twenty-first century (e.g., Caldeira and Wickett, 2003). Oceanic uptake of CO_2 also produces an increase in the seawater concentration of bicarbonate ions (HCO_3^-) and a decrease in the carbonate ion concentration (CO_3^{2-}). As a consequence, the saturation state with respect to calcium carbonate minerals (Ω), which is determined by dividing the in situ ion concentration product of calcium and carbonate ions by an experimentally determined solubility product ($\Omega = [\text{Ca}^{2+}][\text{CO}_3^{2-}]/K_{sp}^*$), will decrease. A lower carbonate saturation state of surface seawater implies that the initial composition of marine sediment pore waters will be closer to undersaturation with

respect to carbonate minerals, and thus, microbial decomposition of less organic material is required to produce undersaturated conditions and subsequent dissolution of carbonate mineral phases in the pore water–sediment system. Furthermore, while most shallow-water environments at present time are supersaturated with respect to calcite, aragonite, and most Mg-calcite phases (in general, Mg-calcite containing 8–12 mol% MgCO_3 or more is more soluble than both calcite and aragonite), surface seawater in high and intermediate latitude environments could become undersaturated with respect to most Mg-calcite phases and even aragonite during the present century. Consequently, as a result of human-induced ocean acidification, dissolution of carbonate minerals and sediments in shallow-water ocean environments is most likely to increase.

Increased dissolution of calcium carbonate minerals and sediments owing to human-induced ocean acidification will most likely occur selectively according to mineral stability. This could lead to a change in the average mineral composition of contemporary carbonate sediments in favor of stable mineral phases such as calcite and low Mg-calcite phases over metastable phases such as aragonite and high Mg-calcite. Although such a transition is slow relative to the rate at which seawater chemistry is changing owing to human activities, evidence for increasing carbonate dissolution and changing sediment composition exists based on numerical model simulations, saturation, and dissolution experiments, and mesocosm experiments, as well as from observations from natural environments. One such environment is Devil's Hole, located within Harrington Sound, Bermuda. During summertime, the water column of Devil's Hole becomes significantly stratified owing to the exponential decrease of solar irradiance as a function of depth. Organic matter produced in the surface mixed layer sinks and is decomposed by microbes in the subthermocline layer. As a consequence, the CO_2 , pH and the seawater saturation state with respect to carbonate minerals in this layer reach values typically not observed for most shallow-water environments today, but similar to values anticipated during the next several decades of the twenty-first century as a result of ocean acidification. In spite of significant production of fine grained Mg-calcite minerals throughout Harrington Sound, for example, by coralline algae, forams, and echinoderms, as well as the abundant occurrence of these mineral particles in sediments located at depths above the thermocline, little evidence exists for their presence in the sediments of Devil's Hole. These mineral phases are most likely selectively dissolved, a conclusion that is also supported by observed changes in seawater carbonate chemistry in the subthermocline layer in Devil's Hole (Figure 5; Neumann, 1965; Andersson et al., 2007).

In addition to the chemical changes imposed on surface seawater owing to rising atmospheric CO_2 , future dissolution of shallow-water carbonate minerals could also increase owing to increased deposition and subsequent increased microbial decomposition of organic matter in marine coastal sediments. Human activities on land have

Biological Control on Diagenesis: Influence of Bacteria and Relevance to Ocean Acidification, Figure 5 (a) Partial pressure of CO_2 (pCO_2) in the water column of Devil's Hole, Harrington Sound, Bermuda. The pCO_2 of the subthermocline layer (gray) is significantly higher than anticipated from equilibrium with the atmosphere owing to microbial decomposition of organic matter. As a result, calcium carbonate minerals are selectively dissolved, which is demonstrated in (b) and (c). The former shows changes in salinity normalized ($S = 36$) calcium concentration ($\Delta[\text{Ca}^{2+}]$) as a function of total alkalinity (ΔnTA) in the subthermocline layer. The observed relationship clearly demonstrates that carbonate dissolution is taking place and the slope of a best fit line (0.44) suggests that the average composition of the dissolving phases has an Mg-content of 12 mol% MgCO_3 . (c) Relative weight percent high Mg-calcite as a function of sediment grain size and depth in Devil's Hole and Harrington Sound. For small grain sizes (<62 μm), the high Mg-calcite content decreases as a function of depth. The figure has been compiled based on data from Neumann (1965), Balzer and Wefer (1981), and Andersson et al. (2007).

significantly increased the amount of organic matter transported via rivers and runoff to the global coastal ocean relative to preindustrial conditions, and the total amount is expected to continue to increase with increased

deposition of this material to the sediments. Furthermore, input of nutrients to the global coastal ocean region have also significantly increased, which may stimulate increased production of organic matter and subsequent deposition of this material to the sediments within this region. As long as surface seawaters are supersaturated with respect to most carbonate phases, microbial decomposition of organic material is the main driver of carbonate dissolution. Consequently, even if the organic material deposited to the sediment–water remained constant, but the microbial activity increased, for example, owing to increasing temperature, carbonate dissolution would also increase. For the next several decades, human activities are likely to continue to lead to acidification of surface seawater and continuous increases in the amount of organic material being deposited to shallow-water sediments, and concurrently with increasing atmospheric concentrations of CO₂, surface and sea surface temperatures are likely to increase with potential increases in microbial and endolithic activity. As a result, dissolution of calcium carbonate minerals, particularly in coastal ocean environments, probably will increase due to all of these forcings. It is possible that under a business as usual scenario of fossil fuel CO₂ emissions, the production of carbonates in the global coastal ocean will be exceeded by their dissolution by year 2150 or earlier.

Summary

Diagenesis refers to those physical, chemical and biological processes that alter the original physical and chemical characteristics and properties of minerals and sediments. Calcium carbonate minerals constitute a substantial fraction of shallow-water sediments and may be subject to significant diagenetic alterations after deposition including dissolution and precipitation reactions. These reactions are largely mediated by microbial processes including oxidation of organic matter under both oxic and anoxic conditions as well as by endoliths, which actively penetrate carbonate substrates. The extent of calcium carbonate dissolution is to a large degree controlled by the amount of organic matter decomposed. Carbonate dissolution is likely to increase in the future in response to human-induced ocean acidification arising from the burning of fossil fuels, but also due to increased riverine transport of organic matter and nutrients to the coastal ocean, enhanced production in situ of organic matter in coastal waters, and subsequent deposition and microbial decomposition of the organic matter in marine sediments.

BIOLOGICAL VOLCANIC ROCK WEATHERING

Charles S. Cockell
 Open University, Milton Keynes, UK

Definition

The biologically induced breakdown of volcanic rocks, including crystalline rocks and glasses.

Volcanic rock weathering and global processes

The weathering of volcanic minerals is known to make a significant contribution to the global silicate weathering budget (Dessert et al., 2003), thus influencing carbon dioxide drawdown and climate control, since carbon

dioxide is consumed in mineral weathering reactions. For example, on land, the Deccan Traps in India, with an estimated area of 10^6 km^2 , is thought to account for about 5% of the global silicate weathering flux (Dessert et al., 2003). In total, basalt rocks may account for over 30% of the global carbon dioxide drawdown in silicate weathering (Gaillardet et al., 1999). The weathering of volcanic rocks also contributes a significant flux of nutrients into the biosphere, and through the weathering of rocks and the formation of clays and secondary minerals, microorganisms accelerate the rate of production of volcanic soils (Andisols) from their parent minerals. Thus, understanding how volcanic rocks weather and what role a biota might play in these processes has importance for understanding climate control, soil formation, and the mechanisms governing the release and distribution of nutrients in the biosphere.

The biological role

The role of plants in accelerating the weathering of volcanic rocks has been established, primarily from studies in Hawaii and Iceland. In Hawaii, plants have been estimated to increase weathering rates by over an order of magnitude compared to unvegetated areas (Cochran and Berner, 1996). In geological terms, the acceleration of weathering caused by plants following their early evolution has been proposed as one mechanism for carbon dioxide drawdown in the late Silurian, resulting in a general cooling trend (Berner, 1992). Plants increase weathering rates by, *inter alia*, physically disaggregating the rock with their roots, the production of rock weathering organic acids, the removal of ions from the subsurface (which changes chemical equilibrium in favor of rock dissolution), and by indirectly producing nutrients and favorable microenvironments for prokaryotes and fungi within the rhizosphere, which themselves weather rocks (see below).

A microbiological involvement in volcanic rock weathering has been established. The primary effect of microorganisms is to accelerate the breakdown of the rock both physically and chemically, often with the formation of secondary minerals such as poorly ordered aluminosilicates and clays (Figure 1). Early studies on the biological weathering of volcanic rocks focused on the role of lichens (Jackson and Keller, 1970; Adamo and Violante, 1991, 2000; Banfield et al., 1999). The earliest study of biological volcanic rock weathering was the seminal study by Fry (1927) who showed that lichens can cause etching, fragmentation, and weakening of obsidian, a silica-rich volcanic glass. Lichens accelerate the physical disaggregation of volcanic rocks as the lichen thallus penetrates the rock substrate. The production of organic acids, organic complexing agents, and the excretion of oxalic acids are just some of the mechanisms by which lichens contribute to the chemical dissolution of the rock substrate (Adamo and Violante, 2000). Oxalic acids are produced by the fungal component in the lichen symbiosis. Calcium oxalate at the lichen–rock interface, although not

Biological Volcanic Rock Weathering, Figure 1 A 1913 basalt flow in Iceland covered in lichens, which play an important role in rock weathering. Image is 20 cm across.

ubiquitous, is one widely reported compound formed on lichen-weathered rocks, which suggests the role of oxalic acids reacting with mineral-derived calcium, although other oxalates, such as copper- and manganese-rich compounds, have been reported.

Lichens have been shown to induce the formation of considerably thicker weathering rinds on crystalline basalts in Hawaii compared to control rocks, which in addition to directly contributing to weathering, may secondarily accelerate the rate of abiotic chemical weathering (Jackson and Keller, 1970). Lichens may also accelerate the dissolution of the silicate from the rock matrix, causing it to be more susceptible to being washed away, promoting the preferential formation of oxides and other secondary minerals from iron. Iron oxide formation is reported at the interface between lichens and basaltic rocks in Hawaii and near Vesuvius, Italy.

Early studies on lichen weathering of volcanic rocks were the first to elucidate two important factors in microbial rock weathering in general: (1) the role of changes in the microenvironment induced by microorganisms at the rock surface, which include changes in pH, water retention, and redox state that alter the equilibrium chemistry of rock dissolution or secondary mineral formation, accelerating rock weathering; and (2) the differential susceptibility of minerals to microbial rock weathering. Calcium-containing plagioclase tends to weather faster than minerals, such as K-feldspars, and these differential effects are determined by the susceptibility of minerals to weathering agents produced by microorganisms or the changes in chemical equilibria.

Since early studies on lichens, many other microorganisms have been examined and found to be capable of accelerating rock weathering. Mechanisms of microbial weathering include: the production of organic acids; the secretion of protons, which changes the local pH at the

rock surface and accelerates weathering; and the production of complexing ligands, such as siderophores, which chelate oxidized iron. It is also becoming clear that these are not merely serendipitous processes resulting from microbial metabolic activity, but that microorganisms actively excrete substances to gain access to nutrients within rocks that might otherwise be limiting, such as major nutrients, including Fe, P, Na, and Ca and trace elements such as K, Ni, or Mn. In addition to the secretion of weathering-promoting substances, by oxidizing or reducing metals during energy acquisition microorganisms can accelerate chemical dissolution or alteration of the rock surface, particularly important examples being iron-oxidizing or reducing bacteria, which use iron as an electron donor or acceptor respectively, and may therefore change the oxidation state of the iron in iron-containing minerals, including olivines and pyroxenes, which form an important component of basaltic mineralogies.

The considerations above apply to both fungi and prokaryotes. In the case of fungi, the penetration of the rock by the hyphae is one primary means by which fungi can invade the interior of a rock and accelerate weathering. Fungi, in particular, are well-known to produce organic acids by which they contribute to rock weathering (Mehta et al., 1978; Gadd, 2006).

Microorganisms do not merely accelerate the weathering of all elements from volcanic rocks. A number of studies have shown that biotic weathering can cause preferential leaching or enrichment of elements at the weathering front or within the sediments produced by volcanic rock weathering. Staudigel et al. (1998), in a study of basaltic glass weathering using a microbial enrichment culture from Loihi seamount, Hawaii, showed that the population of microorganisms, which included heterotrophic bacteria, cyanobacteria, and diatoms, induced an enrichment of calcium in the sediments produced by weathering, but a loss of magnesium, in contrast to the controls which showed the opposite trend. These results, and many others, show that microorganisms can cause a differential rate of leaching of different elements from rocks. Bacteria on their own have been shown to induce the release of iron and manganese. Investigations using a single bacterial species (*Burkholderia fungorum*) (Wu et al., 2007) showed that iron release is induced by changes in the pH at the rock surface. Phosphorus released from the apatite within the basalt rock apparently also helped sustain bacterial growth. All of these experiments show that microorganisms potentially have an important role in modulating the release of different elements from the crust. The oxidation of iron by bacteria in the deep-sea probably gives them an important role in iron cycling and thus weathering of the basalt crust (Edwards et al., 2003).

These data also highlight the general point that although the role of microorganisms in enhancing mineral dissolution has been a major focus of research, it is also important to understand that the weathering of elements from rocks might be influenced by the retardation of elemental release caused by microbial action. For example,

the production of oxidized iron from reduced iron in basaltic minerals such as olivine has been suggested to retard leaching of elements from the rocks (Santelli et al., 2001). Thus, through changes in oxidation states of elements and the production of secondary minerals at rock surfaces, the microbial involvement in volcanic rock weathering may be much more complex than merely enhancing weathering rates, instead changing the leaching rates of specific elements in ways that are either retarded or accelerated compared to abiotic conditions.

The formation of clays and poorly ordered aluminosilicates, such as smectites and allophane-like materials, has been reported around bacterial aggregates in volcanic ash near Sakurajima volcano, Japan (Kawano and Tomita, 2001). The authors, by carrying out batch culture experiments in the laboratory using bacteria isolated from the ash, suggest that the natural populations are involved in biomineralization and therefore play an important part in bacterial alteration of the weathered volcanic ash. In this case mineral formation is likely to have been facilitated by the bacterial cell surface. Although this work did not show active weathering of the primary rock minerals, it illustrates that the formation of clays and other minerals from weathered volcanic ash by microorganisms can play an important role in defining the chemical characteristics of the weathering environment, which itself will alter the environment for other members of the microbial community which may be directly involved in weathering. The work underlines the important link between rock weathering (dissolution and alteration) and mineral formation (biomineralization) during the transition of primary volcanic minerals to soils such that both processes must be considered to truly understand biological volcanic rock weathering and soil neogenesis.

As a logical development of the work of Fry, Herrera et al. (2008) examined bacterial communities within obsidian in Iceland and showed a diverse population of bacteria, which by the use of hybridization probes were shown to be associated with weathering alteration fronts in the rock. Basaltic rocks in terrestrial environments, as with the oceanic environments described above, have been shown to harbor a high prokaryotic diversity (Gomez-Alvarez et al., 2007).

The mechanisms by which microorganisms weather rocks are still based primarily on chemical measurements such as organic acid production or changes in solution pH. New molecular methods are likely to elucidate pathways by which microorganisms can weather rocks and strengthen our understanding of the link between the organisms and the weathering process.

Microbial borings in volcanic glass

Other evidence for a direct role of microorganisms in volcanic rock weathering has been presented in the form of channels or pitted and corroded granular textures, in reactive volcanic glasses. The most commonly studied of these are endolithic borings into volcanic glasses, including

Biological Volcanic Rock Weathering, Figure 2 (a) An outcrop of subglacial basalt glass at Valafell, Iceland. The glass turns conspicuous brown as it transforms into palagonite, a weathering product, (b) “elongate” (tunnellike) weathering features in a vesicle within the outcrop, features (arrow) are at the interface between the palagonite weathering rind (center) and the glass (scale bar 40 μm). The biological origin of such features in different environments is an ongoing controversy.

deep ocean pillow lavas (Fisk et al., 1998; Torsvik et al., 1998; Thorseth et al., 2003; Storrie-Lombardi and Fisk, 2004). Furnes and Staudigel (1999) suggest a dominant role for bioalteration of volcanic glasses in the upper 300 m of oceanic crust. Glass recovered by drilling from more than 250 m below the sea floor shows channels into altered zones that are 1–10 μm wide and penetrate to a depth of 150 μm . In other settings, larger tubes up to 20 μm in diameter and with a depth of 0.5 mm have been observed. The provenance of some of these borings has been controversial since the organisms responsible for the borings have not been cultured. Abiotic ambient inclusion trails, generated by the pressure forcing of mineral grains, such as sulfides, through glass have been suggested as a mechanism for the production of channel features (Figure 2). To address this possibility a number of approaches have been used to show an involvement of biological activity. These include isotopic and elemental analysis. Binding of the nucleic acid stain DAPI (4',6-diamidino-2-phenylindole) to DNA and fluorescence signals obtained using fluorescent in situ hybridization (FISH) probes against both archaea and bacteria in the channels suggest that organisms were responsible for the weathering. Microprobe analysis shows the presence of carbon not associated with carbonates. Low carbon isotope values were also suggested as evidence supporting a biological role in glass alteration.

Early Earth studies and astrobiology

Volcanic terrains would have dominated the landscape of the Archean Earth when life emerged about 3.5 billion years ago. One reason for the keen interest in weathering textures in volcanic glass is the discovery of similar features in ancient Archean volcanic rocks (Furnes et al., 2004). Insofar as channels are morphologically more distinctive than, for example, irregular pitted features, then they might offer evidence for life in early Earth environments. The age dating of materials with biological isotopic signatures has been used to argue that fossils of putative

ancient microbial volcanic glass borers are the same as the age of the rocks (Banerjee et al., 2006). The study of microbial volcanic rock weathering and the textures and minerals left by such interactions may also offer a means to assay ancient Martian terrains for evidence of life (McLoughlin et al., 2007), particularly since Mars, in the absence of plate tectonics, is a planet dominated by volcanic terrains. On a more general level, understanding the interaction of microorganisms with volcanic rocks may provide a means to understand whether the formation of clays and other secondary minerals from basalts on Mars is a purely abiotic process or whether it could ever have been biologically mediated.

Conclusion

Both field and laboratory observations show that plants and microorganisms play an important role in volcanic weathering. The mechanisms by which they achieve this are diverse, but reduce to some common principles which include physical disruption, production of compounds that attack minerals, alteration of chemical equilibria in favor of dissolution, and changes in redox states of metals which favors dissolution. Through their actions, the biota generally accelerates rock weathering, contributing to the release of rock nutrients into the environment and silicate weathering reactions which themselves contribute to long-term carbon dioxide drawdown.

Definition

Biomarkers are the molecular fossils of lipids and other natural products. In sedimentary environments, lipids that escape the remineralization process are commonly chemically reduced to hydrocarbon skeletons. Encased in sedimentary rocks, these skeletons can remain intact over hundreds of millions of years. The structure of biomarkers is often directly related to their precursor lipids and may be diagnostic for a specific group or groups of organisms. Diagnostic biomarkers are used to obtain information about the composition of past (microbial) ecosystems or to determine the first occurrence of organisms in the geological record. As many organisms prefer specific habitats, and as lipid compositions of individual organisms are frequently adjusted to changing physical and chemical conditions, biomarkers may also serve as paleoenvironmental proxies, for example for salinity, temperature, and oxygen availability. In the petroleum industry, biomarkers are utilized to elucidate the extent of biodegradation of crude oil and to obtain information about the thermal history, lithology, depositional environment, and geological age of hydrocarbon source rocks.

Other meanings of "biomarker"

Environmental studies: intact and predominantly functionalized biomolecules in recent sediments, including ancient DNA. *Medicine/pharmacology:* a natural or introduced molecule or substance in an organism that indicates the presence or state of a specific disease. *Toxicology:* a molecule or substance that indicates exposure of an organism to a toxin. *Cell biology:* a molecule that facilitates the detection and isolation of specific cell types. *Genetics:* a DNA fragment that causes disease or contains information about susceptibility to a disease. *Paleobiology:* mineralogical, elemental, isotopic, and morphological indicators for the presence and activity of life in the geological record. *Astrobiology:* anything that could yield experimental evidence for the existence, past or present, of life in our solar system and beyond.

History

Today, crude oil is indisputably recognized as a concentrate of biomarkers and other molecular alteration products of biological organic matter. The hypothesis about a biological origin of petroleum was probably first formulated by the Russian scholar Mikhail Lomonosov in 1757. However, in the nineteenth century, partly based on observations that organic molecules can be generated in the laboratory from inorganic ingredients, most scientists supported an inorganic theory of petroleum formation. The prominent French chemist Marcellin Berthelot suggested in 1866 that petroleum is the product of the reaction of water with inorganic carbides (Berthelot, 1866 and references therein), and Dmitri Mendeleev (1878) insisted that petroleum is abiogenic and forms deep in the Earth's crust. The first studies that yielded systematic evidence for an organic origin of crude oil were carried out by petroleum geologists in the late nineteenth to early twentieth century (see Durand, 2003). Geologists found correlations between the location of petroleum reservoirs and the thermal maturity of associated sedimentary organic matter, and chemists were able to generate petroleum-like oils by heating animal products and black shales under the exclusion of oxygen (pyrolysis). As a consequence of these studies, it was well accepted among North American geologists in the 1930s that petroleum is generated by thermal degradation of organic matter in sedimentary rocks. In Russia in the 1920s, the organic theory of petroleum formation was defended by Vladimir Vernadsky. Vernadsky, clearly ahead of his time and now regarded as one of the founders of organic geochemistry, had already integrated his concepts of petroleum formation into a general framework of biogeochemical cycles (e.g., Vernadsky, 1934). However, the first undeniable proof that bitumen in sedimentary rocks contains molecules of biological origin was presented by Alfred Treibs. In 1934, Treibs isolated a vanadylporphyrin complex (vanadyl-deoxyphylloerythroetioporphyrin **I**)

I Vanadyl-deoxyphylloerythroetioporphyrin

from a bituminous black shale. He found that the nitrogen-carbon skeleton of the red-colored sedimentary porphyrin was virtually identical to the green plant pigment chlorophyll *a* **II**. He showed that the fossil pigment had been

II Chlorophyll *a*

generated from a biogenic precursor through replacement of the central magnesium ion with vanadyl oxide and loss of several functional groups. Alfred Treibs (1936) subsequently solved the degradation pathway of chlorophyll *a* in sedimentary environments, and is now celebrated as the father of biomarker geochemistry.

Crude oil is a complex mixture of thousands of different hydrocarbons and heteroatomic components containing C, S, N, and O. In the 1960s and 1970s, the analysis of such complex systems was facilitated by the rapid development of chemical separation and detection techniques such as gas chromatography (GC), gas chromatography-mass spectroscopy (GC-MS), and elemental analysis. The earliest biomarker studies were strongly inspired by the search for clues to the evolution of early life on the Earth (Barghoorn, 1957; Eglinton et al., 1964; Meinschein et al., 1964; Barghoorn et al., 1965; Burlingame et al.,

1965; Hoering, 1965; Oró and Nooner, 1967; Kvenvolden and Hodgson, 1969; for a review see Brocks et al., 2003b). However, the main driving force of biomarker research later in the twentieth century was the petroleum industry. Organic geochemists employed biomarkers to understand the transformation of organic matter into petroleum, to estimate the thermal maturity and geological age of reservoir oil, and to correlate crude oil with potential source rocks (e.g., Philippi, 1965; Albrecht and Ourisson, 1969; Hunt, 1979; Tissot and Welte, 1984; Peters and Moldowan, 1993). Flowing from applications in the petroleum industry, and in the spirit of Vernadsky, biomarkers also became of increasing interest in the understanding of remineralization and burial of organic matter as crucial aspects of the global carbon cycle (e.g., Hedges et al., 1997; Eglinton and Repeta, 2004), the study of organisms and metabolisms that otherwise rarely leave a fossil record (e.g., Moldowan and Talyzina, 1998; Hinrichs et al., 1999; Summons et al., 1999; Kuypers et al., 2001), and as paleoenvironmental proxies (e.g., Brassell et al., 1986; Summons and Powell, 1986; Schouten et al., 2002).

Declining oil prices in 1998 led to the closure of most biomarker laboratories in the petrochemical industry, and biomarker research strongly shifted to universities with a focus on paleoenvironmental and geomicrobiological applications. In these applications, an integration with modern microbiological techniques and genomics will be a crucial aspect of biomarker geochemistry in the future (e.g., Pearson et al., 2003; Sinninghe Damsté et al., 2004b; Rashby et al., 2007).

Formation and alteration of sedimentary organic matter (diagenesis)

In most planktonic environments, organic carbon from primary producers is nearly quantitatively remineralized back to carbon dioxide and water. On an average less than 0.1% permanently accumulate in bottom sediments (Holser et al., 1988). Most biogenic compounds such as carbohydrates, proteins, nucleic acids, and small metabolites are prone to biological degradation under most conditions and are recycled rapidly back to carbon dioxide and water. Molecules that escape the mineralization process are commonly altered by diagenetic processes in the water column and subsequently, in the sediment. Diagenesis includes a multitude of chemical and biological reactions that lead to the formation of macromolecular aggregates from smaller molecules through condensation and cross-linking reactions, but also to fragmentation, oxidation, reduction, isomerization, and epimerization products (Tissot and Welte, 1984). The relative concentration of different alteration products depends on prevailing physical and chemical conditions in the sediment during and after burial. Analysis of the diagenetic products may, thus, yield information for example, about redox conditions and the presence of catalytic substances such as active mineral surfaces. Under prevailing reducing conditions and over

geological periods of time, biolipids eventually lose their functional groups and are transformed to hydrocarbon

III Bacteriohopanepolyols (BHP)

IV Pentakishomohopane

skeletons (e.g., hopanepolyols **III** to hopanes **IV**, or okenone **V** to okenane **VI**). The hydrocarbon products may remain stable over hundreds of millions of years encased in sedimentary rock.

The exact chemical nature of organic matter in sediments primarily depends on the composition of the source organisms and the mechanisms of preservation. In the so-called selective preservation pathway, molecules that are highly resistant to chemical and biological degradation, such as aliphatic algal biopolymers or cuticular waxes of plant leaves, have a high potential to escape remineralization and may form a major fraction of sedimentary organic matter (Tegelaar et al., 1989; De Leeuw et al., 2006). Smaller molecular building blocks, including monomers generated by hydrolysis of biopolymers, may undergo random condensation to a highly cross-linked macromolecular product that is resistant to further degradation (degradation/recondensation pathway) (e.g., Larter and Douglas, 1980; Tissot and Welte, 1984). Under transitory oxidizing conditions, fatty acids and other lipids may also become cross-linked via ether and carbon-carbon bonds to form resistant aliphatic geomacromolecules ("oxidative polymerization pathway") (e.g., Kuypers et al., 2002; Versteegh et al., 2004). One of the most

significant pathways for the preservation of biomarkers in sediments is natural sulfurization (or natural vulcanization) (Sinninghe Damsté and De Leeuw, 1990). In anoxic environments, bacterial sulfate reduction may lead to the accumulation of hydrogen sulfide and polysulfides. These reduced sulfur species can react with functional groups of organic molecules during early stages of diagenesis, either already in an anoxic water column or in the sediment. Abiotic addition of hydrogen sulfide to double bonds followed by reductive desulfurization is a crucial mechanism in the transformation of labile, oxygen-sensitive lipids into their more stable reduced counterparts (Hebting et al., 2006). Intramolecular incorporation of inorganic sulfur may also lead to the generation of small sulfur-containing molecules that are more resistant to biodegradation, and intermolecular vulcanization may protect smaller molecules by incorporation into a macromolecular network via sulfide and polysulfide bridges (e.g., Adam et al., 1993; Kohnen et al., 1993; Schaeffer et al., 1995; Wakeham et al., 1995). Finally, lithology also has an important influence on the presence and preservation of biomarkers. High concentrations of well-preserved organic matter are most commonly found in fine grained sedimentary rocks such as shales and marls. This has several reasons. Firstly, very fine suspended mineral particles and particulate organic matter have similar hydrodynamic properties and are likely to be deposited at the same location. Secondly, organic matter has a high affinity to clay minerals, and adsorption to mineral surfaces protects organic matter against attack by heterotrophic microorganisms and digestive enzymes, a phenomenon described as the “sorpitive protection pathway.” Thirdly, the fineness of clay particles prevents the circulation of oxygenated water in the sediment, promoting development of anoxic and sulfidic conditions that exclude aerobic heterotrophic organisms and support natural sulfurization.

Thermal alteration of biomarkers and sedimentary organic matter (catagenesis)

The aggregates that form through degradation/recondensation, oxidative polymerization, and natural sulfurization, coalesce with degradation-resistant biopolymers to form kerogen. Kerogen is a highly complex, amorphous macromolecular network of organic matter in sedimentary rocks. Viewed in thin section, it commonly has a yellow, brown, or black color, depending on thermal maturity (De Leeuw and Largeau, 1993). With accumulation of sediment over the top and increasing depth of burial, geothermal heat will induce catagenesis, the thermal alteration and degradation of sedimentary organic matter. The cracking of chemical bonds in kerogen releases smaller molecular fragments that may form a liquid bitumen phase. Formally, bitumen is defined as the fraction of organic matter in sediments and sedimentary rocks that can be extracted using organic solvents. Bitumen released by the thermal decomposition of kerogen typically consists of saturated and aromatic hydrocarbons, including biomarkers, and

lower concentrations of polar (NSO) compounds. Carbon–sulfur and sulfur–sulfur bonds in kerogen are cleaved at relatively low temperatures ($\sim 60^{\circ}\text{C}$), while biomarkers covalently attached to kerogen via carbon–oxygen and carbon–carbon bonds are released at progressively higher temperatures (e.g., Koopmans et al., 1997). Increasing pressure, partially caused by the release of carbon dioxide and methane from kerogen, may eventually lead to the expulsion of liquid hydrocarbons from the source rock and their possible release at hydrocarbon seeps or accumulation in oil reservoirs.

At catagenic temperatures, hydrocarbon biomarkers also undergo thermal isomerization, epimerization, and cracking reactions, and the relative concentration of the thermal alteration products can be used to elucidate the thermal history of bitumen and crude oil. Thus, maturity parameters based on biomarkers and other compounds are used in the petroleum industry to estimate the oil- and gas-generation potential of sedimentary basins. A large variety of different maturity parameters for different temperature stages is available and is summarized in Peters et al. (2004). For instance, the ratio of $22S/(22S + 22R)$ isomers of $17\alpha(\text{H})$ -homohopanes measures the gradual transformation of the biological $22R$ configuration to the more stable $22S$ epimer (see carbon atom marked “*” in **IV**). The $22S/(22S + 22R)$ ratio reaches a thermodynamic equilibrium at a value of ~ 0.6 , indicating a thermal maturity roughly corresponding to the early phase of oil generation (e.g., Zumberge, 1987). However, it is not possible to translate biomarker maturity parameters into absolute temperatures, as the rates of molecular isomerization and degradation also strongly depend on the availability of catalytically active mineral surfaces and reactive species such as free radicals. Therefore, biomarker maturity parameters may be widely different in rocks of different lithology and need to be recalibrated for different basins and formations.

Destruction of biomarkers at high temperatures (metagenesis)

One of the most intriguing topics in biogeology is the examination of early microbial ecosystems using molecular fossils extracted from Precambrian rocks (>542 Ma [million years]). The oldest clearly indigenous bitumens come from the ~ 2.5 Ga (billion years) old Mt McRae Shale of the Hamersley Group in northwestern Australia (Brocks et al., 2003a). However, these bitumens were severely altered by pyrolytic temperatures and predominantly contain polycyclic aromatic hydrocarbons. The oldest molecules of proven provenance that contain biological information come from the 1.64 Ga old Barney Creek formation of the McArthur Basin in northern Australia (Summons et al., 1988). The distribution of biomarkers in the Barney Creek formation is distinct from younger bitumens and strongly dominated by bacterial lipids and pigments (Brocks et al., 2005). While the biomarkers of the Barney Creek formation are clearly

indigenous (Brocks et al., 2008), reports of biomarkers from older successions have to be regarded with caution as the concentration of extractable hydrocarbons are commonly minute and molecular maturity parameters are inconsistent with the thermal history of the rock. Moreover, the extracted biomarkers are often found concentrated on rock surfaces (Brocks et al., 2008) and their composition is always conspicuously similar to Phanerozoic petroleum products (e.g., Brocks et al., 2003b).

All known sedimentary successions older than ~1.8 Ga have suffered burial metamorphism to zeolite facies or higher, probably at minimum temperatures of 175–280°C. At these temperatures, metagenetic processes transform kerogen to a black, hydrogen-poor, and highly aromatic carbon phase, and residual bitumen is cracked to gas and expelled from the rock. However, the existence of residual biomarkers in rocks heated to about 220°C is theoretically not impossible. Modern deep-subsurface petroleum reservoirs produce commercial quantities of oil at present-day temperatures of up to 200°C, and these oils apparently still contain intact biomarkers. Biomarkers were also observed in bitumens extracted from sedimentary rocks that currently exist at temperatures of 200–223°C (for a review see Brocks and Summons, 2004). The persistence of aliphatic hydrocarbons over geological periods of time at up to 250°C is also supported by kinetic models of petroleum degradation (Pepper and Dodd, 1995; Domíné et al., 2002). Therefore, if pockets of organic-rich sedimentary rocks of Paleoproterozoic to Archean age have escaped temperatures above ~220°C, it should still be possible to discover intact molecular fossils to reconstruct the Earth's oldest microbial ecosystems.

Biological interpretation of biomarkers

Most fossil hydrocarbons have multiple biological precursors that are distinguished by different functional groups and stereochemistries. Moreover, most of these biolipids may occur in a wide range of organisms that are not necessarily closely related. Therefore, for a meaningful interpretation of molecular fossils, it is crucial to identify all extant biological sources.

Some biomarkers contain little biological information because they are abundant across all domains of life. For example, the fossil hydrocarbon β -carotane **VII** contains

VII β -Carotane

virtually no taxonomic information. There are several hundred different biological carotenoids with a β -carotane skeleton that are distinguished by different combinations of functional groups such as double and triple bonds, oxo-, hydroxy-, epoxy-, and carboxy-groups and functional ornamentations such as carbohydrate side chains (e.g., Liaaen-Jensen, 1979). These carotenoids

occur across a vast array of lineages in all three domains of life, and most are likely to yield β -carotane **VII** during diagenesis. Therefore, without additional information, β -carotane can not be assigned to any particular biological source.

In contrast to the ubiquitous occurrence of carotenoids with the β -carotane skeleton, the only known potential precursor of okenane **VI** is the purple-red colored carotenoid okenone **V**. As okenone is exclusively known from planktonic species of Chromatiaceae, a family of purple sulfur bacteria, it is interpreted as a diagnostic marker for this group of organisms (Brocks and Schaeffer, 2008). Isorenieratene **VIII**, an aromatic carotenoid like okenane

VIII Isorenieratene

VI, is an intermediate case. The known biological precursor isorenieratene **IX** is the major accessory pigment in

IX Isorenieratene

brown strains of green sulfur bacteria (Chlorobiaceae). Chlorobiaceae are anoxygenic phototrophs and strictly require anaerobic and sulfidic conditions in the presence of light. In planktonic environments, Chlorobiaceae inhabit a zone in the chemocline of stratified waters wherever sulfidic conditions arise into the light penetrated zone (photic zone euxinia). Therefore, isorenieratene is commonly interpreted as a biomarker for Chlorobiaceae and photic zone euxinia (see below). However, a second potential microbial source of aromatic carotenoids with the isorenieratene skeleton are genera of the actinobacterial order Actinomycetales, such as *Mycobacterium*, *Streptomyces*, and *Brevibacterium*. For instance, the orange-colored growths on the surface of cheese is often due to isorenieratene, 3-hydroxyisorenieratene, and 3,3'-dihydroxyisorenieratene from *Brevibacterium linens*, an actinomycete that belongs to the cheese ripening flora (Guyomarc'h et al., 2000). Generally, Actinomycetales are regarded as a microbial group that is restricted to terrestrial environments, particularly soils. However, the group is also known to be ubiquitous, and occasionally abundant, in marine environments (Ward and Bora, 2006). Actinomycetales were detected in the marine water column, in marine snow, in sea sediments, including deep sea sediments, and as symbionts in vertebrates and invertebrates, particularly sponges. It is not yet known just how widespread aromatic carotenoids in marine actinomycetes are. However, at least *Streptomyces griseus*, an actinomycete known from terrestrial as well as marine environments, has the capacity to biosynthesize

isorenieratene (Krügel et al., 1999). Therefore, the fraction of isorenieratene in marine sediments that is derived from terrestrial and marine actinomycetes may be significant, and an actinomycetal origin of isorenieratene in sedimentary rocks from marine depositional environments can not be ruled out.

The occurrence of isorenieratene in distantly related groups of bacteria, Actinomycetales and Chlorobiaceae, highlights our lack of understanding of the distribution of genes involved in carotenoid biosynthesis in extant organisms. For a full interpretation of isorenieratene, we have to learn whether isorenieratene biosynthesis was present in the common ancestor of Chlorobiaceae and Actinomycetales, whether the biosynthetic capacity was transferred horizontally between the two groups, or whether the pathways developed independently. While these questions may best be answered in the future using genomic information, isorenieratene derived from Chlorobiaceae can principally be distinguished from other sources by a diagnostic isotopic enrichment in ^{13}C (Summons and Powell, 1987; Grice et al., 1996a) (also see *Biomarkers (Organic, Compound-Specific Isotopes)*).

In summary, strictly, biomarkers have to be interpreted as indicators for biosynthetic pathways, not as markers for taxonomic groups. In the above example, isorenieratene is a biomarker for β -carotene desaturase, the enzyme responsible for the convergence of β -carotene to isorenieratene, and for *crtU*, the gene that codes for this enzyme. In some cases, it is possible to discriminate between different biological sources of a biomarker using carbon isotopic compositions (see also *Biomarkers (Organic, Compound-Specific Isotopes)*).

Biomarkers for the domains bacteria, archaea, and eukarya

A selection of biologically informative molecular fossils, their potential biological origins and environmental interpretations are summarized in Table 1 (more comprehensive accumulations can be found in Peters and Moldowan [1993], Brocks and Summons [2004], and Peters et al. [2004]). Table 1 also includes biomarkers that are not hydrocarbons but are stable over geological periods of time such as maleimides **X** and archaeal

X Maleimides

XI Archaeal

XII Crenarchaeol

glycerol ethers (**XI** and **XII**). Molecules with limited or no biological information were not included.

Biomarkers of eukaryotes

Next to bacterial hopanoids, eukaryotic steroids are probably the most common polycyclic biomarkers in the geological record. Sterols, such as cholesterol, ergosterol, and sitosterol, are essential membrane components of all eukaryotic organisms. Eukaryotes produce a large variety of different sterols that are distinguished by the number and position of double bonds, hydroxy-, oxo- and alkyl-groups and other, often complex, substituents. Functionalized sterols detected in recent sediments can be diagnostic for a wide range of taxonomic groups, particularly algae (e.g., Volkman, 2003). However, the number of different diagenetic hydrocarbon products is comparatively low (Table 1). The most abundant steranes in bitumens and oils from the late Neoproterozoic to the Cenozoic are cholestane **XIIIa** (C_{27}), ergostane **XIIIb**

XIII Steranes

(24-methylcholestane, C_{28}) and stigmastane **XIIIc** (24-ethylcholestane, C_{29}). Biological precursors of cholestane are abundant in animals and red algae (Rhodophyceae), and precursors of ergostane occur in fungi and several groups of algae, including coccolithophorids and diatoms, while sterols with the stigmastane skeleton are very widespread in higher plants, eustigmatophytes, chrysophytes, and green algae (Chlorophyceae) (Volkman, 1986; Volkman, 2003). However, C_{27} to C_{29} sterols are not restricted to these organisms and occur across all major eukaryotic clades. Even individual organisms may contain sterols with all three carbon skeletons. Thus, cholestanes, ergostanes, and stigmastanes in sedimentary rocks are not specific for any particular group of eukarya. However, the relative abundance of these three sterols shows systematic variations through the Phanerozoic and can be used to obtain an estimate of the age of crude oil (Grantham and Wakefield, 1988).

The biosynthetic capacity to produce steroids also occurs in at least three independent groups of bacteria, the Myxococcales, Methylococcales, and Planctomycetales.

Biomarkers (Molecular Fossils), Table 1 Diagnostic biomarkers and their biological and environmental interpretation

Group of organisms	Biomarker or biomarker pattern	Environmental interpretation and age constraints	Other known potential sources	Further information ^a
Eukarya				
Eukaryotes in general	Ergostane XIIIb , stigmastane XIIIc and their aromatic analogs Cholestane XIIIa and aromatic analogs	Most environments, Neoproterozoic to present	Possible minor contribution from myxococcales (myxobacteria)	(Volkman et al., 1998; Volkman, 2003; Summons et al., 2006) (Kohl et al., 1983; Bode et al., 2003)
Pelagophyte algae ("brown tides" and Sarcinochrysidales)	24- <i>n</i> -Propylcholestane XIIIId	Commonly found only in marine environments		(Moldowan et al., 1990)
Dinoflagellates	4-Methylergostane, 4-methylstigmastane Dinosterane XIV	Mostly Mesozoic and Cenozoic (minor concentrations in Paleozoic, possibly of "protodinoflagellate" origin)	Minor component in other eukaryotes Rare in diatoms	(Volkman, 2003) (Robinson et al., 1984; Volkman et al., 1993; Moldowan and Talyzina, 1998)
Diatoms	24-Norcholestane (C ₂₆)	Cretaceous to Cenozoic		(Holba et al., 1998a, b)
Centric diatoms (genus <i>Rhizosolenia</i>)	C ₂₅ XV and C ₃₀ highly branched isoprenoid (HBI) alkanes	Marine environments, Upper Turonian to present	C ₂₅ HBI in pennate diatoms	(Nichols et al., 1988; Volkman et al., 1994; Sinninghe Damsté et al., 2004b)
Pennate diatoms (phylogenetic cluster including <i>Haslea</i> , <i>Pleurosigma</i> , <i>Navicula</i>)	C ₂₅ HBI alkanes XV	Marine environments	Centric diatoms (genus <i>Rhizosolenia</i>)	(Nichols et al., 1988; Sinninghe Damsté et al., 2004b)
Prymnesiophyte algae	C ₃₇ -C ₃₉ di- to tetra-unsaturated alkenones	The degree of unsaturation changes with water temperature, and this is used in the photic zone temperature proxy U _k ³⁷		(Brassell et al., 1986)
<i>Botryococcus braunii</i> (Chlorophyte alga)	Botryococcanes XVI , cyclobotryococcanes, and polymethylsqualanes Macrocyclic C ₁₅ -C ₃₄ alkanes without carbon number preference	Fresh to brackish water, Tertiary Fresh to brackish water, Tertiary		(Metzger et al., 1985; Huang et al., 1988; Metzger and Largeau, 1999; Summons et al., 2002) (Audino et al., 2002)
<i>Gloeocapsomorpha prisca</i> (uncertain affinity, possibly an alga)	Outstanding concentrations of n-C ₁₅ , n-C ₁₇ , and n-C ₁₉	Cambrian to Devonian		(Fowler, 1992; Blokker et al., 2001)
Ciliates	Gammacerane XVII	The main source is possibly bacterivorous ciliates inhabiting the chemocline of stratified waters	Gammacerane precursors were also observed in a fungus, a fern, and the ubiquitous α -proteobacterium <i>Rhodopseudomonas</i>	(Ten Haven et al., 1989; Sinninghe Damsté et al., 1995)
Terrestrial plants in general	<i>n</i> -Alkanes > C ₂₅ with odd-over-even carbon number preference, derived from higher plant waxes	Proximity to terrestrial organic matter sources; post-Silurian age	Non-marine algae	(Hedberg, 1968; Tissot and Welte, 1984)

Biomarkers (Molecular Fossils), Table 1 (Continued)

Group of organisms	Biomarker or biomarker pattern	Environmental interpretation and age constraints	Other known potential sources	Further information ^a
	Lupane, various plant sources	Common in coal and lignites, Cretaceous to Cenozoic		(Wang and Simoneit, 1990)
	Isopimarane, retene, simonellite, eudesmane, and fichtelite		Possible occurrence in algae and microorganisms	(Peters et al., 2004)
Angiosperms	Oleanane XVIII , precursors are betulins, taraxerenes, and others triterpenoids	Predominantly Upper Cretaceous to Cenozoic	Precursors also occur in lichens and ferns in minor concentrations	(Moldowan et al., 1994)
Angiosperms (e.g., dipterocarpaceae)	Cadinanes, bicadinanes XIX (from degradation of polycadinene resins)	Carboniferous to Cenozoic		(Cox et al., 1986; Van Aarssen et al., 1992)
Conifers	Phyllocladanes, beyeran, kaurane, and atisane	Devonian to Cenozoic, often abundant in coal	Lower concentrations in other land plants and possibly algae	(Noble et al., 1985)
Sponges (demospongiae)	24-Isopropylcholestane XIIIe	Neoproterozoic to present, with higher relative abundance in the late Neoproterozoic to early Cambrian		(McCaffrey et al., 1994; Love et al., 2009)
Archaea				
Archaea in general	C ₃₁ -C ₄₀ head-to-head linked acyclic isoprenoids (e.g., XXI), archaeol XI , and other glycerol ethers Abundant squalane XX , abundant regular acyclic isoprenoids		Bacteria and eukaryotes, but commonly in lower concentrations	
Marine pelagic Crenarchaeota	2,6,15,19-Tetramethylicosane (TMI) Crenarchaeol XII	Only reported from a Mid-Cretaceous oceanic anoxic event First appearance in the Cretaceous		(Vink et al., 1998; Kuypers et al., 2001) (Kuypers et al., 2001)
Haloarchaea	Regular acyclic isoprenoids with 21–30 carbon atoms	Evaporitic environments, salt lakes	Other archaea	(Grice et al., 1998b)
Anaerobic methane oxidizers (ANME)	Crocetane XXII	Typical habitats are subsea gas sources, gas hydrates, and mud volcanoes	Degradation product of diaromatic carotenoids	(Thiel et al., 1999; Bian et al., 2001)
Methanogenic and methanotrophic archaea	2,6,10,15,19-Pentamethylicosane (PMI)			(Schouten et al., 1997; Elvert et al., 1999; Thiel et al., 1999)
Bacteria				
Bacteria in general	C ₃₀ -hopanes		Some cryptogams, ferns, mosses, lichens, filamentous fungi, and protists	(Rohmer et al., 1984)
	Hopanes with extended side chain (homohopanes (C ₃₁) – pentakishomohopane IVa (C ₃₅))			(Rohmer et al., 1984; Ourisson and Albrecht, 1992)

Biomarkers (Molecular Fossils), Table 1 (Continued)

Group of organisms	Biomarker or biomarker pattern	Environmental interpretation and age constraints	Other known potential sources	Further information ^a
Cyanobacteria	Abundant monomethylalkanes and dimethylalkanes		Other bacteria, sponges	(Shiea et al., 1990; Kenig et al., 1995; Köster et al., 1999; Dembitsky et al., 2001)
	2-Methylhopanes IVc		Pseudomonadales, rhizobiales	(Summons et al., 1999; Rashby et al., 2007)
Type-I methanotrophic bacteria (methylococcaceae)	3 β -Methylhopanes IVb		Methylotrophs, acetic acid bacteria	(Zundel and Rohmer, 1985a, b, c; Summons and Jahnke, 1992; Farrimond et al., 2000)
	4-Methylcholestanes, 4,4-dimethylcholestanes		Dinoflagellates, minor component in all eukaryotes	(Bird et al., 1971; Brocks et al., 2005)
Green sulfur bacteria (Chlorobiaceae)	Chlorobactane XXIII (green pigmented species)	Anoxic and sulfidic conditions in the presence of light in microbial mats or planktonic environments (photic zone euxinia)		(Schaeffer et al., 1997; Grice et al., 1998a, 2005; Brocks et al., 2005)
	Isorenieratane VIII (brown pigmented species)	Photic zone euxinia	Some sponges, Actinomycetales	(Hartgers et al., 1993; Grice et al., 1996a; Koopmans et al., 1996b; Bosch et al., 1998; Pancost et al., 1998; Putschew et al., 1998; Simons and Kenig, 2001; Sinninghe Damsté et al., 2001)
	β -Isorenieratane (brown pigmented species)	Photic zone euxinia		(Grice et al., 1998a; Brocks and Schaeffer, 2008)
	2,3,6-Trimethyl aryl isoprenoids – (cleavage products of VIII and XXIII)	Photic zone euxinia	Aromatization and degradation of β -carotene	(Summons and Powell, 1986; Requejo et al., 1992; Summons and Powell, 1992; Hartgers et al., 1993; Koopmans et al., 1996a)
	Palaerenieratane XXIV and 3,4,5- trimethyl aryl isoprenoids	Photic zone euxinia; restricted to the Paleozoic?		(Requejo et al., 1992; Hartgers et al., 1993)
	3-Isobutyl-4-methylmaleimide Xc		Chloroflexaceae	(Grice et al., 1996b, 1997; Pancost et al., 2002)
Purple sulfur bacteria (Chromatiaceae)	Okenane VI	Photic zone euxinia, planktonic conditions		(Brocks et al., 2005; Brocks and Schaeffer, 2008)
	2,3,4-Trimethyl aryl isoprenoids	Photic zone euxinia	Cyanobacterial synechocanthin?	(Brocks et al., 2005; Graham and Bryant, 2008)
	Renieratane	Photic zone euxinia	Sponges or sponge symbionts	(Brocks and Schaeffer, 2008)
	Renierapurpurane	Photic zone euxinia	Sponges or sponge symbionts, cyanobacterial synechocanthin?	(Graham and Bryant, 2008; Brocks and Schaeffer, 2008)
Gemmata (Planctomycetales)	Lanostane		Minor in all eukaryotes and steroid producing bacteria (Pearson et al., 2003)	(Pearson et al., 2003)
Phototrophs in general	Pristane, phytane	From chlorophylls of cyanobacteria and phototrophic eukaryotes, BChl <i>a</i> and <i>b</i> of phototrophic bacteria	Tocopherols and other acyclic isoprenoids, archaeal membrane lipids	(Peters et al., 2004)

Biomarkers (Molecular Fossils), Table 1 (Continued)

Group of organisms	Biomarker or biomarker pattern	Environmental interpretation and age constraints	Other known potential sources	Further information ^a
	3,4-Dimethyl Xa and 3-ethyl-4-methylmaleimides Xb	Chlorophylls and bacteriochlorophylls		(Grice et al., 1996b)
<i>Anthropogenic contaminants</i>				
Polyethylene plastic bags	5,5-Diethylalkanes with odd-over-even carbon number preference, and other branched alkanes with quaternary carbon (BAQCs) Alkylcyclopentanes with even-over-odd carbon number preference			(Grosjean and Logan, 2007; Brocks et al., 2008) (Grosjean and Logan, 2007; Brocks et al., 2008)
Detergents	Phenylalkanes			(Harvey et al., 1985)
Plasticizers	Phthalates			(Mayer et al., 1972)

^aadditional information taken from Peters et al. (2004) and Brocks and Summons (2004)

Phylogenetic trees of oxidosqualene cyclase (OSC), the first enzyme in the sterol biosynthetic pathway, show that sterol biosynthesis was laterally transferred between eukaryotes and the three bacterial groups (Pearson et al., 2003). However, bacteria do not possess the enzymes required to alkylate the steroid side chain, and fossils steroids alkylated at C-23 or C-24 (e.g., ergostane **XIIIb**, stigmastane **XIIIc** and dinosterane **XIV**) must still be regarded as diagnostic biomarkers for eukaryotes.

XIV Dinosterane

Pelagophytes and dinoflagellates. In contrast to C₂₇ to C₂₉ steranes, steroids with 30 carbon atoms can be highly specific. For example, 24-*n*-propylcholestane **XIIIId** is a diagnostic marker for algae of the order Sarcinochrysidales and the so-called brown tide algae (Moldowan et al., 1990). These organisms are strictly marine, and 24-*n*-propylcholestane is, thus, regarded as a reliable indicator for marine depositional conditions. Another steroid with a unique carbon skeleton is dinosterane **XIV** (4,23,24-trimethylcholestane). The biological precursors of dinosterane **XIV**, dinosterol, and related compounds (Robinson et al., 1984), are the dominant sterols in many dinoflagellate species (see references in Volkman, 2003). Only one other organism, a diatom species, is known to contain sterols with the same carbon skeleton. Therefore, dinosterane is regarded as

a relatively reliable biomarker for dinoflagellates (Summons et al., 1987). In the microfossil record, the first modern dinoflagellates appeared in the Mesozoic, and this is also reflected by a significant increase in dinosterane concentrations in contemporaneous rocks (Moldowan et al., 1996; Moldowan and Talyzina, 1998; Summons et al., 1987, 1992). Traces of dinosteranes in Paleozoic sedimentary rocks were identified as the likely molecular remains of ancestral dinoflagellates (Moldowan et al., 1996; Talyzina et al., 2000). Dinoflagellates are probably also the dominant source of other steranes and aromatic steroid that bear a methyl group at C-4 (4-methylcholestane, 4-methylergostane, and 4-methylstigmastane; compare structure **XIII**). However, these biomarkers are less specific, and multiple other biological sources are known (Volkman, 2003).

Diatoms. An unusual sterane common in post-Jurassic marine sediments is 24-norcholestane. Although the biological precursor lipids remain unknown, indirect evidence points to diatoms as the major source (Holba et al., 1998a). Consistent with this assignment, the relative concentration of 24-norcholestanes in crude oils rises in concert with the radiation of diatoms from the Jurassic to the Tertiary (Holba et al., 1998b). Other specific biomarkers for diatoms are “highly branched isoprenoid” (HBI) alkanes **XV** with 25 and 30 carbon atoms

XV C₂₅ HBI

(e.g., Volkman et al., 1994). The unsaturated precursors of HBI alkanes are found in two discrete phylogenetic clusters of diatoms. C_{25} and C_{30} HBIs occur in centric diatoms of the genus *Rhizosolenia*, and a second cluster, comprising three genera of pennate diatoms, produces C_{25} HBI alkenes (Sinninghe Damsté et al., 2004b). Remarkably, the C_5 building blocks of HBI alkenes in the centric diatoms are biosynthesized using the mevalonate (MVA) pathway, while the isoprene building blocks of HBI alkenes in pennate diatoms are constructed following the methylerythritol (MEP) route (Massé et al., 2004). The distribution of C_{25} HBIs **XV** in marine sediments and petroleum constrains the radiation of rhizosolenid diatoms quite accurately to the Upper Turonian, 91.5 ± 1.5 Ma ago (Sinninghe Damsté et al., 2004b). The biological origin of HBIs in marine sediments with 20, 21, 22, and 26 carbon atoms is still unknown, but diatoms are also a likely source (Sinninghe Damsté et al., 2005). Although C_{20} HBI has been identified in field samples of the green macro algae *Chara* and *Enteromorpha* (Rowland et al., 1985; Jaffé et al., 2001), it is likely derived from epiphytic micro algae colonizing the macrophytes (Volkman et al., 1998; Atahan et al., 2007) (see also *Biomarkers (Organic, Compound-Specific Isotopes)*).

Green algae. The green unicellular microalga *Botryococcus braunii* is found in freshwater, brackish lakes, and reservoirs at varying latitudes (Tyson, 1995 and references therein). Three distinct races (A, B, and L) of this alga are recognized and are classified according to their hydrocarbon composition. The A race biosynthesizes n -alkadienes and trienes with an odd carbon number between C_{25} and C_{31} (Metzger et al., 1986, 1991). The B race produces C_{30} to C_{37} branched isoprenoidal hydrocarbons called botryococcenes giving rise to botryococcanes (e.g., **XVI**) (Maxwell et al., 1968;

XVI Botryococene

Metzger and Largeau, 1999) and a wide variety of cyclobotryococcenes (Metzger et al., 1985; David et al., 1988), and polymethylsqualenes (Summons et al., 2002). The L race makes a C_{40} isoprenoid hydrocarbon, lycop-14(*E*),18(*E*)-diene (Metzger and Casadevall, 1987; Metzger et al., 1991). Macrocyclic alkane biomarkers with 15-34 carbon atoms are derived from *Botryococcus* cell wall material (Audino et al., 2002). Although botryococcanes are quite rare in petroleum, they are among the most specific biomarkers and indicate a lacustrine origin and Tertiary age.

Straight chain alkanes (n -alkanes) are the most abundant class of saturated hydrocarbons in all bitumens and oils that have not suffered biodegradation. n -Alkanes have a vast variety of biological precursors such as saturated and unsaturated fatty acids and their esters, alcohols, alkenes, plant waxes, and polymethylenic biopolymers.

As biochemicals with n -alkyl skeletons occur in all branches across the three domains of life, the structure of single n -alkanes has no taxonomic value (although their carbon and hydrogen isotopic composition may yield valuable environmental and biological clues - see *Biomarkers (Organic, Compound-Specific Isotopes)*). However, some n -alkane profiles, i.e., the relative concentration of n -alkanes with different carbon numbers, can be taxonomically informative. For instance, bitumens and oils from the early Paleozoic often show elevated abundances of n -alkanes with odd carbon numbers in the range n - C_{15} and n - C_{19} . This age diagnostic n -alkane profile is attributed to *Gloeocapsomorpha prisca*, an extinct marine alga (or other organism) of unknown affinity (Hoffmann et al., 1987; Fowler, 1992).

The cell wall of many marine and lacustrine chlorophytes and marine eustigmatophytes is composed of algaenan, an insoluble, polymethylenic macromolecule (Derenne et al., 1992; e.g., Gelin et al., 1997; Blokker et al., 2000). Cracking of algaenan during burial and catagenesis releases large volumes of n -alkanes that contribute significantly to the formation of liquid petroleum (Tegelaar et al., 1989). There is evidence that a major radiation of chlorophytes in the late Neoproterozoic also contributed to the formation of the oldest commercial reservoirs of petroleum (Grantham et al., 1988). These oils are characterized by high concentrations of long-chain n -alkanes derived from the degradation of algaenan or related macromolecules (Klomp, 1986; Fowler and Douglas, 1987; Höld et al., 1999). The same oils contain unprecedented high relative concentrations of stigmastanes **XIIIc**, the major steroid derived from green algae (Volkman, 2003).

Ciliates. Some bacterivorous ciliates produce the pentacyclic triterpenoid tetrahymanol (Harvey and McManus, 1991). The fossil product of tetrahymanol, gammacerane **XVII**, is often abundant in sedimentary rocks

XVII Gammacerane

that were deposited under stratified and anoxic waters (Sinninghe Damsté et al., 1995). In these environments, predatory ciliates may inhabit the chemocline feeding on microaerophilic and anaerobic microorganisms. Gammacerane can reflect the often unusual carbon isotopic composition of the microbial food source (see *Biomarkers (Organic, Compound-Specific Isotopes)*) (Sinninghe Damsté et al., 1995; Grice et al., 1998a).

Terrestrial plants. In the geological record, plant-derived biomarkers start to appear in bitumens and oils from the Devonian, and can be exceedingly abundant in sediments from the late Mesozoic to Cenozoic. The most common plant signature is a suite of n -alkanes derived from plant waxes with more than 27 carbon atoms and a

predominance of odd-over-even carbon numbers (i.e., C_{27} , C_{29} , C_{31} etc.) (Hedberg, 1968). In coals and other sediments with significant input of terrestrial organic matter, high-molecular-weight alkanes with more than 40 and up to 110 carbon atoms are the degradation products of cuticular waxes and plant-derived biopolymers such as cutan and suberan (e.g., Nip et al., 1986; Tegelaar et al., 1995; Del Rio and Philp, 1999). One of the most common polycyclic terpenoids derived from plants is oleanane **XVIII**. Oleanane is a biomarker for flowering plants

XVIII Oleanane

(angiosperms), and the relative concentration of oleanane in bitumens from the early Cretaceous to Tertiary parallels the radiation of angiosperm families, as documented in the pollen record (Moldowan et al., 1994). The thermal degradation of polycadinene resins of tropical angiosperms generates terpenoids of the cadinane family. Cadinane, bicadinanes **XIX**, and tricadinanes are found

XIX Bicadinane

in sedimentary rocks from the Carboniferous to Cenozoic and are potentially diagnostic for Dipterocarpaceae, a group that today comprises mainly tropical lowland rainforest trees (Cox et al., 1986; Van Aarssen et al., 1990). The degradation of conifer resins releases a large variety of bicyclic and tricyclic terpenoids such as phyllocladane, beyerane, kaurane, atisane, retene, and simonellite that are abundant in coal (Table 1). However, many of these biomarkers are also found in lower concentrations in marine sedimentary rocks or rock of pre-Devonian age, and it appears likely that they also have algal or prokaryotic sources. For instance, the triaromatic hydrocarbon retene can be abundant in Tertiary shales and coals, and used to be interpreted as the degradation product of conifer resins (Villar et al., 1988). However, retene was also detected in marine rocks of late Neoproterozoic to early Paleozoic age (Jiang et al., 1995), and in pyrolysis products of algal and cyanobacterial tissue (Wen et al., 2000).

Sponges. Surprisingly, 24-isopropylcholestane **XIIIe**, indicative of the class Demospongiae, is the only known hydrocarbon biomarker that appears to be specific for any group of animals. In the geological record, the concentration of 24-isopropylcholestane **XIIIe** (relative to algal 24-*n*-propylcholestane **XIIIId**) is particularly high

from the latest Neoproterozoic to early Phanerozoic age, a distribution that may reflect the radiation and abundance of early sponges during this time (McCaffrey et al., 1994; Love et al., 2009).

Biomarkers of archaea

Archaea play a key role in the geochemical cycles of hydrogen, nitrogen, methane, and sulfur in a wide variety of marine, lacustrine and terrestrial environments. Although many archaea inhabit "extreme" environments such as hot springs and crystallizer ponds, they are also cosmopolitan inhabitants of the open ocean (e.g., Delong, 1992; Karner et al., 2001). Therefore, it is not unexpected that archaeal biomarkers can be found in a large number of oils and bitumens of all ages. Membrane lipids of archaea are very distinct from eukaryotes and bacteria. They are predominantly based on regular or irregular, acyclic or cyclic isoprenoids commonly bound to a glycerol backbone via ether links. The most common hydrocarbons derived from archaea in mature bitumens and oils are C_{21+} regular acyclic isoprenoids, and squalane **XX**, an

XX Squalane

irregular isoprenoid that comprises two tail-tail linked C_{15} isoprenoid units. Although precursors of these isoprenoids also occur in other organisms, archaea are presumed to be the major source. The abundance of archaeal biomarkers in bitumens is usually low in comparison to eukaryotic and bacterial lipids. However, under specific environmental conditions, archaeal organic matter may constitute a significant fraction of total sedimentary organic carbon, including marine (Kuypers et al., 2001) and hypersaline (Grice et al., 1998b) depositional environments.

Marine Crenarchaeota. According to cell counts based on whole-cell rRNA-targeted fluorescent in situ hybridization, pelagic crenarchaeota constitute ~20% of picoplankton cells in the world ocean, and may even outnumber the bacteria in the mesopelagic and bathypelagic zones (Karner et al., 2001). Cell numbers computed from the concentration of archaeal membrane lipids at different water depth in the Arabian Sea confirm this estimate (Sinninghe Damsté et al., 2002). The membrane lipids of crenarchaeota are typically glycerol dialkyl glycerol tetraethers (GDGTs) (De Rosa and Gambacorta, 1988). GDGTs consist of two glycerol units linked by two tetraetherpenoid (C_{40}) chains that may be acyclic (biphytane **XXI**) or contain one to three cyclopentane moieties.

XXI Biphytane

GDGTs are also biosynthesized by methanogenic and methanotrophic euryarchaeotes, and occur in a

wide variety of environments, including hot springs and cold lakes. However, crenarchaeol **XII**, which is distinguished by the presence of an additional cyclohexane moiety, appears to be a diagnostic biomarker for marine pelagic crenarchaeotes (Sinninghe Damsté et al., 2002). GDGTs are exceptionally stable and have been detected in 140 Ma old rocks from the Upper Jurassic age (Carrillo-Hernandez et al., 2003). During the mid-Cretaceous Oceanic Anoxic Event OAE1b, the ocean may have been dominated by pelagic crenarchaeota (Kuypers et al., 2001). The sediments of OAE1b contain acyclic and cyclic biphytanes as well as intact GDGTs, including crenarchaeol (see also *Biomarkers (Organic, Compound-Specific Isotopes)*).

The rings incorporated into the biphytanyl chains of GDGTs are considered to be a mechanism for temperature adaptation in archaea. Schouten et al. (2002) found that the number of pentacyclic rings in GDGTs (expressed as the biomarker ratio TEX₈₆) is a linear function of annual mean sea surface temperatures. The correlation $T = 10.8 + 56.2 * \text{TEX}_{86}$ is calibrated for temperatures from 5 to 35°C (Kim et al., 2008) and possibly 40°C (Schouten et al., 2007). As an example, TEX₈₆ measurements revealed that average sea surface temperatures in the late Cretaceous were very high, ~15°C in the Arctic ocean (Jenkyns et al., 2004), and >32–36°C at low latitudes in the North Atlantic (Schouten et al., 2003). Temperature measurements on GDGTs also contributed significantly to the understanding of the Paleocene/Eocene thermal maximum (PETM) 55 Ma ago. The PETM was one of the most rapid global heating events in Earth's history. It was accompanied by environmental changes and a sharp global negative carbon isotopic excursion, although the precise order of events remained uncertain for a long time. Sluijs et al. (2007) obtained a high-resolution record of sea surface temperatures across the PETM based on TEX₈₆ from sediments in New Jersey. The record indicated that sea surface temperatures and ecological changes preceded the carbon isotopic excursion by ~3,000 years. This discovery is consistent with the hypothesis that increasing temperatures of marine bottom waters caused dissociation of submarine gas hydrates and injection of isotopically light methane carbon into the atmosphere/ocean system. TEX₈₆ measurements also indicated that sea surface temperatures near the North Pole increased during the PETM from 18 to 23°C, temperatures that are more than 10°C higher than predicted by previous models (Sluijs et al., 2006).

Halophilic archaea. Archaea of the order Halobacteriales are frequently the dominant organisms in hypersaline environments such as salt lakes and pools of evaporating sea water (Oren, 2002). The membrane lipids of extremely halophilic archaea that may thrive at halite concentrations as high as saturation levels, contain glycerol ethers with C₂₀ and C₂₅ regularly branched acyclic isoprenoid side chains (e.g., **XI**). The degradation products of these glycerol ethers are often preserved in sedimentary rocks

associated with halite deposits. For example, the dominant hydrocarbons in Miocene/Pliocene sediments from the Dead Sea Basin, Israel, are regular isoprenoids with 19–25 carbon atoms (Grice et al., 1998b). Halophilic archaea also biosynthesize carotenoids with highly characteristic skeletons with 50 carbon atoms such as bacterioruberin. However, the fossil equivalents of these carotenoids have not yet been detected in the geological record.

Methanogenic and methanotrophic archaea. Methane metabolizing archaea biosynthesize generic glycerol diethers and tetraethers, and diagnostic hydroxyarchaeols, macrocyclic archaeols, and irregularly branched acyclic isoprenoid hydrocarbons such as 2,6,10,15,19-pentamethylcosane (PMI). Methanotrophic archaea oxidize methane under anaerobic conditions in consortium with sulfate reducing bacteria. The sulfate reducers make the process thermodynamically viable by removing the hydrogen that is generated as a by-product of the methanotrophic process. Crocetane **XXII**, an irregular

XXII Crocetane

tail-to-tail linked C₂₀ isoprenoid, is commonly found at methane seeps, and is diagnostic for methanotrophic archaea if it has a light carbon isotopic composition (Greenwood and Summons, 2003). For more details about biomarkers at methane venting sites and of methane metabolizing Archaea, see *Biomarkers (Organic, Compound-Specific Isotopes)*.

Biomarkers of bacteria

By mass, bacterial hopanoids stored in sedimentary organic matter and oil deposits were described as the most abundant natural products on the Earth (Ourisson and Albrecht, 1992). Fossil hopanes **IV** and aromatic hopanoids can be found in virtually all thermally well-preserved bitumens and oils from the Paleoproterozoic to the present. The biological precursors in bacteria are bacteriohopanepolyols **III** with a hydrophilic side chain that is biosynthetically derived from a pentose sugar. The polar side chain commonly carries three to five hydroxy groups and may additionally be ornamented with a terminal amino group, peptidic derivatives, carbohydrates, glucosamines, nitrogenous bases, and many more (Ourisson et al., 1987). Bacteriohopanepolyols are thought to play a role as membrane modifiers analogous to sterols in eukaryotes, but the exact function of the large structural variety of hopanoids remains a major area for future research. Although terpenoids with a C₃₀ hopane skeleton have been observed in some cryptogams, ferns, mosses, lichens, filamentous fungi, and protist, C₃₅ bacteriohopanoids **III** with a pentose-derived side chain appear to be diagnostic for bacteria. Although most hopanoid producers are aerobic, there is now a growing number of reports of anaerobic bacteria that contain

hopanols as well (Sinninghe Damsté et al., 2004a; Fischer et al., 2005). Generally, bacterial lineages that produce hopanoids are widely distributed across phylogenetic trees without apparent systematic patterns, and less than 10% of all species contain the genes required for hopanoid biosynthesis (Pearson et al., 2007). Thus, hopanes in sediments cannot be attributed to any specific bacterial source without additional information (Rohmer et al., 1984; Farrimond et al., 1998). However, hopanoids with alkyl substituents at ring A appear to be limited to a restricted number of groups. For instance, 3-methylhopanoids appear to be exclusive to microaerophilic proteobacteria (acetic acid bacteria, methanotrophs, methylotrophs) (Summons and Jahnke, 1992), and 2-methylhopanoids are abundant in, although not exclusive to, cyanobacteria (Summons et al., 1999).

Cyanobacteria. Many cyanobacteria produce relatively high concentrations of hopanepolyols that are methylated at C-2. The hydrocarbon derivatives of these lipids, 2 α -methylhopanes **IVc**, are found in most oils and bitumens of all ages. To gauge the contribution of cyanobacterial debris to the sedimentary carbon pool, Summons et al. (1999) introduced the 2 α -methylhopane index (2-MHI) that expresses the concentration of C₃₁ 2 α -methylhopane relative to general bacterial C₃₀ hopane. On an average, the 2-MHI is higher in the Proterozoic than the Phanerozoic, consistent with the hypothesis that cyanobacteria played a more significant role as primary producers in the Precambrian (Summons et al., 1999). However, not all cyanobacteria produce hopanoids (Rohmer et al., 1984), and hopanoid biosynthesis in marine cyanobacteria appears to be rare (Pearson et al., 2007). Thus, absence or low concentrations of 2-methylhopanes should not be used as evidence for low activity of these organisms. Moreover, 2-methylbacteriohopanepolyols also occur in methylotrophic and nitrogen fixing proteobacteria. 2-Methylhopanoid biosynthesis in the γ -proteobacterium *Rhodospseudomonas palustris* occurs under anaerobic conditions, and this further complicates the interpretation of 2-MHI as an indicator for oxygenic photosynthesis (Rashby et al., 2007).

Low-molecular-weight (C₁₄–C₁₉) monomethyl alkanes and other acyclic alkanes with one or more alkyl groups occur in all oils and bitumens, but are particularly abundant in the Precambrian and in sediments with remnant microbial mat assemblages (Summons and Walter, 1990). Although methylalkyl compounds occur in many microorganisms, the predominant sources are probably the mono- to tri-methyl branched alkanes that are abundant in extant cyanobacteria (Köster et al., 1999).

Methanotrophs, methylotrophs, and acetic acid bacteria. Several groups of microaerophilic proteobacteria - type-I methanotrophs, methylotrophs, and acetic acid bacteria - biosynthesize hopanoids with an additional methyl group in 3 β -position (Zundel and Rohmer, 1985a; Summons and Jahnke, 1992). Although 3 β -methylhopanes **IVb** in sedimentary rocks and oils may be derived from any of

the above groups, hopanoids of methanotrophs are probably the major source and can be distinguished by a pronounced depletion in ¹³C compared to co-occurring compounds (see *Biomarkers (Organic, Compound-Specific Isotopes)*) (Collister et al., 1992; Jahnke et al., 1999). A second unusual group of lipids produced by type-I methanotrophs are sterols with a cholestane **XIIIa** skeleton (C₂₇) that carry one or two additional methyl groups at C-4 (Bird et al., 1971; Summons and Capon, 1988). 4-methyl and 4,4-dimethyl cholesteroids are also widespread in eukaryotes because they are the early intermediates in the biosynthesis of higher sterols. However, as intermediates, concentrations in eukaryotes are commonly very low, and very high relative concentrations of 4-methyl- and 4,4-dimethylcholestanes and their aromatic analogs in bitumens and oils likely indicate activity of methanotrophic bacteria. The oldest biomarkers of type-I methanotrophic bacteria come from the 1.6 Ga Barney Creek Formation in the McArthur Basin, northern Australia (Brocks et al., 2005). The well-preserved, organic-rich dolostones of the Barney Creek Formation were deposited in a deep rift basin that was, at least intermittently, stratified and sulfidic. In these ancient bitumens, 4-methylated triaromatic cholesteroids constituted >90% of the entire steroid population and, together with high relative concentrations of 3 β -methylhopanes, suggest that aerobic methanotrophic bacteria were abundant members of the microbial community. As aerobic methanotrophs are usually only abundant in sulfate-starved environments (<0.5 mM) (Hoehler et al., 1998), the biomarkers suggest that sulfate concentrations in this Paleoproterozoic basin were well below the present marine level of about 28 mM.

Green sulfur bacteria (Chlorobiaceae). Green sulfur bacteria (Chlorobiaceae) are strictly anaerobic, obligately phototrophic organisms that exclusively utilize photosystem I (PS I). They require, with few exceptions, reduced sulfur species such as sulfide and sulfur as an electron donor. Thus, biomarkers of Chlorobiaceae, including specific aromatic carotenoids and bacteriochlorophyll breakdown products, are proxies for anoxic and sulfidic conditions in the presence of light, either in microbial mats or marine and lacustrine stratified waters (photic zone euxinia). Green pigmented Chlorobiaceae contain the carotenoids chlorobactene and hydroxychlorobactene, and the diagenetic product of these pigments, chlorobactane **XXIII**, is regarded as a highly diagnostic

XXIII Chlorobactane

biomarker. The major carotenoids of brown pigmented strains of Chlorobiaceae are isorenieratene **IX** and β -isorenieratene that form the geologically stable fossil analogs isorenieratane **VIII** and β -isorenieratene. Isorenieratene **IX** also occurs in Actinomycetes, bacteria

that predominantly inhabit soil but have also been observed in marine sediments. However, Chlorobiaceae and Actinomycetes follow different carbon fixation pathways, and the carbon isotopic compositions of isorenieratane **VIII** can be used to determine the exact biological source (see *Biomarkers (Organic, Compound-Specific Isotopes)*). An unusual isomer of isorenieratane **VIII**, palaerenieratane **XXIV** with a 3,4,5-trimethyl aryl

XXIV Palaerenieratane

substitution pattern, is exclusively known from sedimentary rocks of Paleozoic age. A biological precursor of palaerenieratane **XXIV** has not yet been discovered in extant organisms, but a strong carbon isotopic enrichment indicative of carbon assimilation via the reversed tricarboxylic acid (TCA) suggests that it is derived from unknown Chlorobiaceae (Hartgers et al., 1993).

Other biomarkers that are diagnostic for Chlorobiaceae are degradation products of specific bacteriochlorophylls (BChl). BChl *c* and *d* exclusively occur in green filamentous bacteria (Chloroflexaceae) and Chlorobiaceae. BChl *e* (as a major pigment) is restricted to brown strains of Chlorobiaceae. During diagenesis, oxidative degradation of the tetrapyrrole skeleton of chlorophylls can lead to the formation of maleimides (1H-pyrrole-2,5-diones) that are highly stable under geological conditions (Grice et al., 1996b). While Chl *a* found in oxygenic phototrophs yields 3,4-dimethyl **Xa** and 3-ethyl-4-methylmaleimides **Xb** upon oxidation, BChls *c*, *d* and *e* yield the diagnostic biomarker 3-isobutyl-4-methylmaleimide **Xc**. Whether **Xc** in a particular sample is derived from Chlorobiaceae or Chloroflexaceae can be distinguished by compound-specific carbon isotopic measurements (Grice et al., 1996b) (see also *Biomarkers (Organic, Compound-Specific Isotopes)*).

Purple sulfur bacteria (Chromatiales). Purple sulfur bacteria (families Chromatiaceae and Ectothiorhodospiraceae) are anoxygenic phototrophs that form a well-separated group in the γ -subgroup of Proteobacteria. Although purple sulfur bacteria are generally metabolically more versatile than green sulfur bacteria, they also predominantly utilize sulfide and sulfur as their electron source. In microbial mats and stratified water bodies, they commonly inhabit a layer above green sulfur bacteria within the light penetrated zone directly beneath the oxic–anoxic interface. Twelve known genera of Chromatiaceae contain the purple coloured carotenoid okenone **V** that possesses a unique carbon skeleton with a 2,3,4-trimethyl aryl substitution pattern (Brocks and Schaeffer, 2008). The molecular fossil, okenane **VI**, is believed to be a diagnostic biomarker for Chromatiaceae (Brocks et al., 2005). Okenone has not been detected in microbial mat environments, and it may function as

a specific accessory pigment for planktonic Chromatiaceae, adjusting the light harvesting systems to lighting conditions at relatively shallow water depth of less than ~25 m. Thus, okenane can be regarded as a biomarker for euxinic water systems with particularly shallow stratification.

The oldest biomarkers of green and purple sulfur bacteria were discovered in the Paleoproterozoic Barney Creek Formation in the McArthur Basin in northern Australia (Brocks et al., 2005). The 1.64 Ga old dolostones were deposited in a deep intracratonic rift basin that probably only had restricted connection to the ocean. Extracts of sedimentary rocks yielded high relative concentrations of okenane **VI** and chlorobactane **XXIII**, but only minor amounts of isorenieratane **VIII**. In comparison with modern ecosystems with similar pigment distributions, the biomarkers probably indicate a basin with a very shallow thermocline (~12 m). Chromatiaceae probably formed major blooms in a layer directly beneath the anoxic–oxic boundary, underlain by a layer of green pigmented Chromatiaceae and, yet deeper, minor communities of brown pigmented strains. In modern ecosystems, a strong activity of Chromatiaceae and green pigmented Chlorobiaceae is often associated with a low abundance of oxygenic phototrophs in the overlying water column. In the Barney Creek Formation, this is confirmed by a paucity of biomarkers diagnostic for eukaryotic algae (Brocks and Schaeffer, 2008).

Conclusions

The development of new metabolic pathways that permitted microorganisms to utilize previously untapped energy sources, such as iron reduction, oxygenic photosynthesis, and methanotrophy probably had profound effects on the chemical evolution of Earth's atmosphere, crust, and oceans. It is a major aim of geobiology to correlate these chemical and isotopic changes in the geological record with the appearance of new microbial physiologies. One of the most informative methodologies to recognize the radiation of a new microbial group in the geological record is molecular fossils. To assign molecular fossils to specific organisms, or groups of organisms, we rely on information about the occurrence of precursor lipids in extant organisms, and almost all this information is derived from organisms that were grown in culture. However, according to some estimates, more than 99% of microorganisms currently defy isolation, and their physiologies, ecological roles, and lipid biosynthetic capacities remain largely unknown. This gap in knowledge is the main limitation for the application and interpretation of biomarkers. Promising ways to fill this gap are offered by cultivation-independent genomic and microbiological techniques such as 16S rRNA clone libraries, group-specific fluorescence in situ hybridization (FISH), and simultaneous community genomic (Tyson et al., 2004) and proteomic (Ram et al., 2005) studies. The technologies will help to describe which organisms are present in natural environments,

which groups are quantitatively important, and what are their major lipid products under specific conditions (Brocks and Banfield, 2009). Ideally, it should become possible to collate quantitative data about the rate of horizontal gene transfer and convergent evolution in lipid biosynthetic pathways, and this should make it possible to estimate the probability with which a biomarker from an ancient rock can be assigned to a specific biological source.

Stable isotopes of individual biomarkers

Definition

Stable isotopes as opposed to radiogenic (unstable) isotopes do not decay; thus, their natural abundances stay relatively constant, even over geological time. However, variations in stable isotopic composition, or isotopic fractionation, occur in nature as a consequence of chemical and physical processes, due to different isotopes of an element having different physical and chemical properties. Equilibrium processes and kinetic processes can lead to isotopic fractionation. Equilibrium isotope effects occur as a result of temperature-dependent equilibrium isotope-exchange reactions resulting in a change of the isotope distribution between different chemical materials, between varying phases, or between individual molecules (Hoefs, 1987). For example, the equilibrium reaction:

Subscripts indicate that A and B contain either the light (1) or heavy (2) isotope.

In these cases, there is no net variation in the chemical process, i.e., the products are chemically similar to the reactants, with the exception that the stable isotopes are distributed differently between them. An example is the evaporation/condensation cycle of water as shown in the following equation (D stands for “deuterium,” the heavy hydrogen isotope, ²H)

This physical process results in a change in the distribution of hydrogen and oxygen isotopes in both liquid and vapor phases. Kinetic fractionation occurs when water vapor is removed before condensation occurs. Kinetic isotope effects occur when an irreversible chemical reaction takes place resulting in a change in the chemical process. As a simple example, a unidirectional chemical reaction always shows a depletion of the heavy isotope in the reaction products relative to the reactants. This occurs due to the slower reaction rate of the heavier isotopic species. For example, in a reaction of reactant A to product B, there may be two (or more) competing unidirectional isotopic reactions:

where k is the rate constant.

In this theoretical example, the rate-determining step involves the cleavage of a bond. It is generally easier to cleave the bonds of molecules that contain the lighter isotopes because the vibrational frequency of such bonds tends to be elevated. Thus, in this case, $k_1 > k_2$, and therefore more of the lighter isotope will be incorporated into the product. A similar, although physical, process is the evaporation of water where the vapor is removed immediately. This process involves the following three competing unidirectional isotopic reactions:

In this case, $k_1 > k_2 > k_3$ because the lighter isotopic species of water evaporate preferentially. Thus, the net process results in water vapor that is enriched in protium (^1H).

Standards and notation

Stable isotopic compositions are expressed as a delta (δ) value (e.g., $\delta^{13}\text{C}$ for carbon, δD for hydrogen) in units of per mil (‰) or parts per thousand (Equation 1). Stable carbon and hydrogen isotopic compositions are determined not as absolute isotopic abundances, but as ratios of a heavy isotope (e.g., ^{13}C , D) to a light isotope (e.g., ^{12}C , H) relative to an international standard.

$$\delta^{13}\text{C} = [(R_{\text{sample}})/(R_{\text{standard}}) - 1] \times 1000\text{‰}, \quad (1) \\ R = ^{13}\text{C}/^{12}\text{C} \text{ or } \text{D}/\text{H}.$$

For example, stable carbon isotopic compositions are determined as a ratio of ^{13}C to a ^{12}C relative to the international Vienna Pee Dee Belemnite (VPDB) calibrated to the

original marine limestone from the Pee Dee formation in South Carolina (USA). This original PDB standard was exhausted and has been replaced by calibrating another carbonate standard (NBS-19) relative to PDB (Urey et al., 1951; Craig, 1957). The new calibration scale is called “VPDB” (Vienna PDB). For stable hydrogen isotopic composition, the ratio is deuterium ^2H , or D, to protium relative to Standard Mean Ocean Water (SMOW). SMOW is thought to represent an average isotopic composition of the world’s oceans based on data collected over a decade (Werner and Brand, 2001). However, the standard is no longer available as a reference material, and therefore was defined relative to an additional water standard (NBS-1, also exhausted) which differs by 47.6‰ from the present scale (Werner and Brand, 2001). Thus a new reference material was developed with an isotopic composition equivalent to that of SMOW, which led to the current “VSMOW” (Vienna SMOW) scale. An alternative primary international standard for δD determinations is Standard Light Antarctic Precipitation (SLAP, δD of -428‰).

Compound-specific isotopes

The stable isotopic composition of organic matter is determined by its genetic origin. The elements hydrogen and carbon are the main constituents of organic matter and play key roles in many biochemical, ecological, environmental, hydrologic, and atmospheric processes. Therefore, stable isotopic compositions preserved in organic matter can provide powerful insights into these processes. Early isotopic investigations were chiefly based on bulk carbon isotope analysis. Continuous flow isotope ratio monitoring gas-chromatography mass spectrometry (irm-GCMS) also commonly referred to as compound-specific isotope analysis (CSIA) is important for determining the stable isotopic compositions of individual organic components in complex mixtures (e.g., petroleum, natural gases, sediments, soils, groundwater, potable waters, and extracts from plants and other media). As with gas-chromatography-mass spectrometry (GC-MS), compounds are separated according to mass differences. In an isotope ratio mass spectrometer, different isotopes of the same compound are separated based on relative mass differences. A gas analyte stream is prepared and it is then ionized by an ion source. The electron multiplier detects the ions of different isotope masses over a range of mass/charge ratios. This technique has been applied for several decades to the analysis of biomarkers of lipids (also see Chapter *Biomarkers (Molecular Fossils)*) and other natural products such as chlorophylls/bacteriochlorophylls found in intricate mixtures of petroleum, and in bitumens and kerogens extracted from sediments and sedimentary rocks. John Hayes pioneered the development of CSIA in the field of organic geochemistry based on his practice and principles of isotopic measurement and calibration, inter- and intramolecular isotopic distributions and

a fundamental understanding of carbon and hydrogen isotopic fractionation within biosynthetic pathways (Matthews and Hayes, 1978; Hayes, 1983, 1993, 2001; Summons et al., 2008). The first carbon isotopic measurements of individual fossil hydrocarbons was performed by Summons and Powell in 1986, and within the fields of organic geochemistry and biogeochemistry such measurements have become important for palaeoclimate reconstruction and are also used to elucidate aspects of biogeochemical cycling within a broad range of microbially mediated processes (Freeman et al., 1990; Summons et al., 1994; Summons et al., 1996).

Instrumentation

The irm-GCMS, whereby the gas chromatograph (GC) is linked to an isotope ratio mass spectrometer via a combustion interface for determining $^{13}\text{C}/^{12}\text{C}$ of individual organic components, in complex mixtures of petroleum and organic extracts from sedimentary material (Matthews and Hayes, 1978). The combustion interface either consists of a quartz tube containing CuO pellets (850°C) or a ceramic tube containing twisted CuO/Pt wires (850°C) (Matthews and Hayes, 1978; Hayes, 1983) yielding a gas analyte of CO_2 and by-product H_2O for each GC-separated component. H_2O is removed either with a Nafion trap or a liquid N_2 trap at -100°C . The isotope ratio mass spectrometer measures the abundances of the ions m/z 44 ($^{12}\text{CO}_2$), 45 ($^{13}\text{CO}_2$) and 46 ($^{12}\text{C}^{18}\text{O}^{16}\text{O}_2$). D/H CSIA requires that a GC is linked to an isotope ratio mass spectrometer via a pyrolysis furnace – either ceramic with a glassy carbon coating ($1,400^{\circ}\text{C}$) or quartz packed with sieved chromium pellets ($1,050^{\circ}\text{C}$) yielding a gas analyte of H_2 for each GC-separated component (e.g., Prosser and Scrimgeour, 1995; Burgøyne and Hayes, 1998). For this application the mass spectrometer measures the abundances of the ions m/z 3 (^2DH) and 2 ($^1\text{H}_2$). Contributions from H_3^+ produced in the ion source are corrected following m/z 3 analyses at two different pressures of the H_2 reference gas to determine the H_3^+ correction factor. Developments also include irm-GCMS instruments capable of measuring $^{15}\text{N}/^{14}\text{N}$ and $^{18}\text{O}/^{16}\text{O}$ (Merrit, 1993; Brand et al., 1994; Kashiyaama et al., 2007).

In brief, biomarkers are the molecular fossils of biolipids and other natural products and are diagnostic for certain organisms such as algae, higher plants (e.g., Brassell et al., 1986), methanotrophic bacteria (Summons et al., 1994), and a wide range of other heterotrophic organisms (Grice et al., 1998a and references therein). Many biomarkers can be detected by GC-MS, and stable isotopic values are now routinely measured with the advent of CSIA. The identity, isomeric arrangement and stable isotopic composition of biomarkers have been used in studies of petroleum and sedimentary organic matter to assess biological sources, and paleoenvironmental and depositional information.

In the petroleum industry, CSIA has been used for source rock–oil, oil–gas, and gas–gas correlation studies (e.g., Fusetti et al., 2010a, b).

Separation techniques

To obtain accurate and precise isotope ratios, components must be amenable to analysis using GC. However, biomarkers may be chemically bound to kerogen, or they may be highly functionalized, making them difficult to resolve by GC, thus presenting significant analytical challenges for CSIA. With the advent of hydropyrolysis (HyPy) (e.g., Love et al., 2005 and references therein) and micro-scale-sealed-vessel pyrolysis (MSSV) (Horsfield and Dueppenbecker, 1991; Beramendi-Orosco et al., 2006; Greenwood et al., 2006; Meredith et al., 2006) we can now release biomarkers from kerogen under mild conditions and convert highly functionalized lipids into hydrocarbons that are more amenable to GC-MS and CSIA.

Sample preferences for CSIA include: (1) low-molecular weight compounds, (2) at least 60 ng component concentration, and (3) complete chromatographic separation (i.e., to baseline) of component peaks of interest. CSIA has much more critical requirements for the GC resolution of products than standard molecular characterization by GC-MS. Compounds containing a higher propensity of ^{13}C atoms elute slightly earlier than their isotopically lighter counterparts. Thus, incomplete chromatographic resolution results in an overlap between $^{12}\text{CO}_2$ and $^{13}\text{CO}_2$ analyte signals from the co-eluting compounds, making it impossible to accurately determine their individual isotopic values. To avoid co-elution, separation techniques such as molecular sieving isolate fractions based on molecular size (e.g., 5A, ZSM-5, 13X, Armanios et al., 1993; Ellis et al., 1994; West et al., 1990; Grice et al., 2001; Audino et al., 2004; Tolosa and Ogrinc, 2007; Grice et al., 2008a). Other separation techniques include preparative thin layer chromatography (TLC), liquid chromatography (LC), gel permeation chromatography (Inaba and Suzuki, 2003), and High Performance LC-MS (HPLC-MS) (e.g., Smittenberg and Sachs, 2007). However, in petroleum, there are many minor components that are not routinely analyzed by CSIA due to lack of techniques to isolate suitable fractions. Even after fractionation of petroleum using state-of-the-art separation techniques, the resulting mixtures can still be extraordinarily complex and may not be amenable to CSIA. It is also important to establish that separation procedures do not cause isotopic fractionation.

For polar components, it is usually necessary to derivatize and improve chromatographic separation using derivatization agents such as BSTFA (N-O-*bis*(trimethylsilyl) trifluoroacetamide) (Jones et al., 1991) or MTBSTFA (N-(*tert*-butyldimethylsilyl)-N-methyltrifluoroacetamide) (e.g., Grice et al., 1996a). For CSIA, choice of the derivatization reagent is crucial to ensure accurate $\delta^{13}\text{C}$ analysis

(see Rieley, 1994 for a review). Imprecision is introduced into the δ value of the compound with derivatization groups of unknown $^{13}\text{C}/^{12}\text{C}$ contribution. A derivatization reagent which only introduces a small number of carbon atoms is desirable for minimizing the imprecision (Rieley, 1994). The $\delta^{13}\text{C}$ value for the derivatization reagent can be determined by $\delta^{13}\text{C}$ analyses of standards before and after derivatization and applying the mass balance equation as described by Jones et al. (1991). Monosaccharides can be derivatized using methylboronic acid and BSTFA (van Dongen et al., 2001). This method has proven to be useful for $\delta^{13}\text{C}$ analyses of arabinose, xylose, fucose, fructose, and glucose.

Isotopic interpretation of biomarkers

The $\delta^{13}\text{C}$ and δD of individual biomolecules in sediments and organisms depends on the complex isotopic fractionation associated with the biosynthetic network that is responsible for their formation (e.g., Hayes, 1993; Collister et al., 1994; Hayes, 2001; Monson and Hayes, 1982; Melzer and Schmidt, 1987; Schwender et al., 1996; Sessions et al., 1999; Chikaraishi et al., 2004a, b; Liu and Huang, 2005; Chikaraishi and Naraoka, 2006; Rommerskirchen et al., 2006). Lipids produced by different biosynthetic pathways can differ in $\delta^{13}\text{C}$ by up to 20‰ within an individual organism (e.g., Summons et al., 1994; Schouten et al., 1998; and van der Meer et al., 1998). However, the exact mechanisms leading to these isotopic differences are not well-understood (Hayes, 2001). Other factors that impose carbon isotopic variation in living organisms include the partial pressure of CO_2 ($p\text{CO}_2$), cell size and geometry (Goericke et al., 1994; Popp et al., 1998), the growth rate of phytoplanktonic cells (Laws et al., 1995; Bidigare et al., 1997), and in land plants, water-use efficiency as, e.g., observed in C_3 , C_4 , and CAM plants (Ehleringer et al., 1993).

When reconstructing environments of deposition based on CSIA $^{13}\text{C}/^{12}\text{C}$ of biomarkers it is important to determine an isotopic reference point against which values for various components can be compared. C_{27} steranes and the C_{20} regular isoprenoid phytane are especially useful components since they are commonly reported in lacustrine and marine settings and mostly deriving from C_{27} sterols and chlorophyll *a*, respectively. Hence, $\delta^{13}\text{C}$ of sedimentary steranes and phytane provide a reference point for lipid components predominantly biosynthesized by the algae in the upper water column. In sediment samples from the Permian Kupferschiefer, the $\delta^{13}\text{C}$ of phytane was found to be similar to co-occurring algal-derived cholestane, consistent with a common algal origin for both biomarkers. However, other sources of phytane cannot be excluded, such as chlorophyll *a* of cyanobacteria (Grice et al., 1996b), and C_{27} sterols are also a significant component in the cell membranes of most animals. The Permian Kupferschiefer also contains the biomarker methyl ethyl maleimide, an oxidative degradation product predominantly derived from the macrocycle of chlorophyll *a* (Grice et al., 1996b, 1997). The maleimide was

3.5–4.5‰ more enriched in ^{13}C than phytane from the phytol side chain, a magnitude of difference to be expected from a common chlorophyll origin (Grice et al., 1996b, 1997). When using CSIA $^{13}\text{C}/^{12}\text{C}$ of biomarkers in sedimentary organic matter to reconstruct paleoenvironments, it is understood that stable carbon isotopic fractionation effects associated with the biosynthesis of sterols and isoprenoids as well as cell sizes and geometry of the phytoplankton community, may be averaged out for sediment samples covering hundreds to millions of years. CSIA $^{13}\text{C}/^{12}\text{C}$ has also been applied to feeding studies. Zooplankton feeding on algae does not alter the stable carbon isotopic compositions of the algal lipids, which these organisms consume, retain, metabolize to cholesterol, and/or excrete (e.g., Grice et al., 1998a). Zooplanktons are selective feeders and the preferred algae may have distinct $\delta^{13}\text{C}$. $\delta^{13}\text{C}$ signals of sterols (sterols and steranes) in sediments are probably representative of a phytoplankton mixture, although individual communities of the mixture have different $\delta^{13}\text{C}$ compositions. This limitation should be borne in mind when using $\delta^{13}\text{C}$ of sterols and steranes as isotopic reference points. Furthermore, a co-occurrence of algal lipids can complicate the interpretation of $\delta^{13}\text{C}$ of phytoplankton biomarkers, since individual algal species are known to biosynthesize lipids with quite different carbon isotopic compositions (see Schouten et al., 1998). Thus, differences between phytane and cholestane in organic matter may not be due to different source organisms, since there may be distinct effects associated with the biosynthesis of each by a single organism. Schouten et al. (1998), however, still suggest cholestane is one of the most suitable isotopic reference points of the primary producers living in the euphotic zone of ancient water columns. Until recently, phytol and its diagenetic alteration products were thought to be useful indicators of phytoplanktonic isotopic reference points (e.g., Freeman et al., 1990; Hayes et al., 1990; Grice et al., 1998a). However, recent phytol isotopic data reported from a range of algae, land plants, and bacteria suggest that the disparities in carbon isotopic value of phytane and of a given degradation (e.g., the C_{19} isoprenoid pristane) may be due to isotopic heterogeneity within molecules (Schouten et al., 2008). However, the stable carbon isotopic composition will depend on whether pristane and phytane are exclusively derived from phytol or if there are additional sources (e.g., archaeal diether lipids, tocopherols, bacteriochlorophylls *a/b*) with potentially different stable carbon isotopic compositions (see below).

It is well-established that diagenetic and catagenetic processes over geological time (millions of years) promote significant hydrogen exchange between organic biomolecules in the surrounding environment with formation water (Rigby et al., 1981; Alexander et al., 1984; Schimmelmann et al., 1999; Leif and Simoneit, 2000; Schimmelmann et al., 2001; Sessions et al., 2004; Dawson et al., 2005). D/H studies of extant organisms have shown that biosynthetically produced

lipids are depleted in D relative to the total biomass (e.g., Estep and Hoering, 1980). Furthermore, polyisoprenoid lipids are depleted in D relative to *n*-alkyl lipids (Estep and Hoering, 1980; Sessions et al., 1999). The magnitude of the fractionation between growth water and *n*-alkyl lipids is ca. -150‰ , while the fractionation between water and isoprenoid lipids is ca. -235‰ (e.g., Smith and Epstein, 1970; e.g., Estep and Hoering, 1980; Sessions et al., 1999).

D/H of biomarkers can be strongly influenced by thermal maturation reflecting a strong relationship with the alteration of indigenous D/H signatures. Dawson et al. (2005) demonstrated the use of D/H ratios of sedimentary hydrocarbons (*n*-alkanes, pristane, and phytane) to evaluate the maturity of source-rocks and crude oils from the Perth Basin (WA). Pristane and phytane were significantly depleted in D compared to *n*-alkanes, although this difference reduces with increasing maturity due to thermally promoted isotopic exchange. The *n*-alkane–isoprenoid D/H signature of crude oils of different source facies was consistent with values associated with mature–late mature sediments, i.e., representative of the peak oil-generative window. The average D/H ratios for Pr and Ph correlate well with % equivalent vitrinite reflectance, which further supports a relationship between maturation and isotopic enrichment in isoprenoids. The work by Dawson et al. (2005, 2007) and Pedentchouk et al. (2006) suggests that the D/H measurement of sedimentary hydrocarbons may represent a useful maturity parameter which also accounts for different source-effects.

Green algae

Biomarkers derived from *Botryococcus braunii* (also see Chapter *Biomarkers (Molecular Fossils)*) have been shown to be significantly enriched in ^{13}C compared with other phytoplanktonic biomarkers in crude oils (Dowling et al., 1995) and sediments (Boreham et al., 1994; Huang et al., 1995; Grice et al., 1998b; Huang et al., 1999; Audino et al., 2001a; Summons et al., 2002). High $\delta^{13}\text{C}$ have also been demonstrated in *Botryococcus braunii* cultures (Summons et al., 1996), and although the reasons for this anomaly remain ambiguous, there are several potential explanations proposed, including (1) isotopic fractionation accompanying photosynthesis in *Botryococcus braunii* may not be fully expressed due to limiting internal $p\text{CO}_2$, (2) the thick outer walls of these microalgae may limit the diffusion rates for CO_2 , thereby enriching biomass in ^{13}C (Boreham et al., 1994), and (3) *Botryococcus braunii* utilize a ^{13}C -rich bicarbonate source (Huang et al., 1999 and references therein). A biomarker of *Botryococcus braunii* in a sediment dated to the last glacial maximum (Huang et al., 1999) was found to be significantly enriched in ^{13}C ($\delta^{13}\text{C} = -5\text{‰}$) which was attributed to low atmospheric $p\text{CO}_2$ leading to depletion of dissolved CO_2 and therefore causing *Botryococcus braunii* to assimilate isotopically heavier bicarbonate in its lake environment. In

some hypersaline sediments of Miocene/Pliocene age from the Mount Sdom Formation, Dead Sea, Israel (Grice et al., 1998b) a novel series of organosulfur compounds (OSC) derived from the functionalized lipids of *Botryococcus braunii* races B and L were recognized. The B and L race derived components were 13–20‰ and 5–7‰, respectively more enriched in ^{13}C than marine phytoplanktonic biomarkers pointing to differing seasonal blooms for each race. Other unique biomarkers from *Botryococcus braunii* include at least four homologous series of monomethylalkanes (MMAs) ranging from C_{23} to C_{31+} in the bitumens and kerogens of a number of torbanites (Audino et al., 2001a). Stable carbon isotopic data support a source derived directly from botryals of *Botryococcus braunii* race A. These compounds are also symptomatic of extreme heterotrophic reworking of ^{13}C -rich *Botryococcus braunii* algal biomass. Macrocyclic alkanes (Audino et al., 2001a, 2002a, b; Grice et al., 2001) have been previously identified in torbanites and Indonesian crude oils containing remains of the freshwater alga. Based on $\delta^{13}\text{C}$ data it has been suggested that these compounds are derived from the algaenan of *Botryococcus braunii* formed by an olefin metathesis reaction. The hydrogen isotopic ratios of lipids from *Botryococcus braunii*, including alkadienes, botryococenes, heptadecenes, fatty acids, and phytadiene, closely follow the δD of the assimilated water (Zhang et al., 2007). A δD saw-toothed profile for odd and even *n*-alkanes in the torbanites is attributed to a dual-source system, a predominant *B. braunii* input with a second minor contribution from land plants (Dawson et al., 2004). δD of *n*-alkanes also reflected the depositional palaeolatitude/palaeoclimate of the sediments, attributed to the δD composition of meteoric waters in the environment where the sediments were deposited. For example, Torbanites deposited in a mid-latitude region under cool-temperate conditions contain *n*-alkanes with δD values falling in between those of *n*-alkanes from tropical (isotopically heavier) and glacial (isotopically lighter) environments (Dawson et al., 2004).

Photosynthetic sulfur bacteria

Green sulfur bacteria (Chlorobiaceae) fix CO_2 via the reversed tricarboxylic acid cycle (Evans et al., 1966) leading to an enrichment of ^{13}C in biomass (Quandt et al., 1977; Sirevag et al., 1977) by around 15‰ relative to oxygenic phototrophic organisms utilizing the Calvin–Benson cycle for carbon fixation (e.g., Summons and Powell, 1986, 1987; Sinninghe Damsté et al., 1993; Hartgers et al., 1994a, b; Grice et al., 1996a, 1997). Chlorobiaceae also produce a range of relatively specific biomarkers such as the carotenoid derivatives isorenieratane and chlorobactane, certain aryl isoprenoids, methyl isobutyl maleimide, and farnesane (see Chapter *Biomarkers (Molecular Fossils)*). Detection of carbon isotopically strongly enriched lipids of this kind

in the rock record is evidence for the activity of green sulfur bacteria. As Chlorobiaceae are strictly anaerobic phototrophs and utilize reduced sulfur species as electron donor, isotopically heavy isorenieratane and related aromatic compounds in geological samples have been widely used as molecular indicators for the presence of H₂S in the zone of light penetration ("PZE" photic zone euxinia). In addition, more recently the biomarker crocetane in thermally mature samples has been attributed to carotenoids of Chlorobiaceae (Maslen et al., 2009).

The characteristic isotopic enrichment of Chlorobiaceae has also been observed in chlorobactane derived from the accessory pigment chlorobactene (Grice et al., 1998d) and in certain bacteriochlorophylls (Grice et al., 1996a, b). The structurally specific bacteriochlorophylls (BChl) of Chlorobiaceae (BChl *c*, *d* (*e*)) give rise to biomarkers such as 3-methyl-4-isobutylmaleimide and farnesane derived from the bacteriochlorophyll macrocycle and lipid farnesyl side chain, respectively. Farnesane has been reported to be depleted in ¹³C by about 3‰ compared to methyl isobutyl maleimide consistent with an origin of bacteriochlorophylls of Chlorobiaceae (Grice et al., 1996a, b). These data are supported by a recent study of the isotopic composition of lipids at different depths of saline meromictic Lake Kaiike, Japan (Ohkouchi et al., 2007). The carbon isotopic compositions of tetrapyrroles (chlorophyllides) were considerably enriched in ¹³C relative to the side chains (phytol or farnesol) of chlorophyll *a*, bacteriochlorophyll *a*, and bacteriochlorophylls *e*.

Along with S isotopic evidence from sedimentary pyrite minerals, Chlorobiaceae-derived biomarkers have provided evidence for the presence of PZE conditions during the largest extinction event of the Phanerozoic, at the end-Permian mass extinction (Grice et al., 2005a; Nabbefeld et al., 2010a, b). It has been proposed that the release of toxic H₂S to the ocean surface and atmosphere played a critical role in the extinction and protracted recovery (Knoll et al., 1996). Similar conditions during the end-Permian have been reported in the contemporaneous seas off southern China, W. Canada, E. Greenland, and Kashmir-Tibet (Summons et al., 2006). It has been proposed by Kump et al. (2005) that a chemocline upward excursion probably provided a trigger for the extinction, releasing toxic H₂S to the ocean surface and atmosphere.

Lipids derived from purple sulfur bacteria of the family Chromatiaceae, such as the carotenoid pigment okenone (Schaeffer et al., 1997; Brocks and Schaeffer, 2008), may be significantly depleted in ¹³C compared to phytoplankton markers. Carbon fixation in both Chromatiaceae and phytoplankton follows the Calvin–Benson Cycle and should, in principle, lead to similar carbon isotopic compositions of organic matter. Chromatiaceae inhabit deeper layers just beneath the thermocline of stratified euxinic waters where they may utilize CO₂ derived from remineralized organic matter, and a CO₂ source that is typically strongly depleted in ¹³C.

Dinoflagellates

CSIA ¹³C/¹²C has been used to distinguish dinoflagellates and methanotrophic bacterial sources of sedimentary 4-methyl and 4, 4-dimethylcholesteroids (Bird et al., 1971). The δ¹³C values of the 4-methylsteroids in Chinese hypersaline lacustrine sediments (Grice et al., 1998d) are significantly enriched in ¹³C compared to co-occurring phytoplankton markers. These data are inconsistent with an origin from methanotrophic bacteria (see below).

In a study by Ramos et al. (2003) CSIA of individual fatty acids was performed to establish the transfer of primary photosynthate from the euphotic zone to benthic/hyperbenthic environments in Conception Bay (Newfoundland, Canada). δ¹³C of fatty acids were highest at the height of the phytoplanktonic bloom, and became ¹³C-depleted at the end of the bloom cycle.

Diatoms

Highly branched C₂₅ and C₃₀ isoprenoid (HBI) alkane biomarkers of sedimentary organic matter (Robson and Rowland, 1986; Sinninghe Damsté et al., 1989) are sourced from diatoms (Nichols et al., 1988; Volkman et al., 1992, 1994). The δ¹³C of these components are heavier than other phytoplankton biomarkers (e.g., Freeman et al., 1994; Summons et al., 1993), which have been attributed to a seasonal blooming of certain diatoms. Non-blooming diatoms are also reported to use a bicarbonate pumping mechanism leading to their biomass being ¹³C-rich (Summons et al., 1993). In samples of particulate organic matter from the water column and sediments from Ellis Fjord (eastern Antarctica) the C_{25:2} HBI alkene-assumed precursor of C₂₅ HBI was found to have an enriched stable carbon isotopic composition consistent with a diatom source, probably belonging to the *Navicula* genus in the sea ice (Sinninghe Damsté et al., 2007).

Epiphytic algae

C₂₀ HBI and its monoene have been reported in both marine and freshwater sediments (Rowland et al., 1985). The structural similarity of the C₂₀ HBI to C₂₅ and C₃₀ HBIs, led Sinninghe Damsté et al. (2005) to propose a common diatom source for each of these. The C₂₀ HBI has not been identified in cultured diatoms (Volkman et al., 1998; Sinninghe Damsté et al., 2005), but has been identified in field samples of macrophytes *Chara* sp. and *Enteromorpha prolifera* (Rowland et al., 1985; Jaffe et al., 2001) pointing toward an epiphytic algal source (Volkman et al., 1998). Similar δ¹³C and δD of the C₂₀ HBI to the C₃₁ *n*-alkane attributed to land plants waxes in a series of Holocene sediments from China (Atahan et al., 2007; Grice et al., 2008b, 2009) implies a common source organism, or organisms utilizing similar carbon sources. Therefore, an epiphytic algal source is suggested for C₂₀ HBI.

Haptophytes

Long-chain C_{37} and C_{38} alkenones (de Leeuw et al., 1980; Volkman et al., 1980; Rechka and Maxwell, 1988a, b; Thiel et al., 1997) are biosynthesized by certain haptophytes (e.g., Marlowe et al., 1990). The individual stable carbon isotopic compositions of alkenones, in combination with other data, have been used to assess ancient pCO_2 levels (Jasper and Hayes, 1990; Jasper et al., 1994). CSIA $^{13}C/^{12}C$ data for haptophytes are consistent with active uptake of bicarbonate, followed by intracellular carbonic anhydrase-catalyzed conversion of bicarbonate to CO_2 for cellular utilization by these organisms (Werne and Hollander, 2004). The ratio of long-chain alkenones and their stable carbon isotopic compositions are unaffected by zooplankton herbivory (Grice et al., 1998a). $\delta^{13}C$ (ca. -36‰) of abundant C_{37} and C_{38} n -alkanes in a Chinese hypersaline lacustrine (Eocene-Paleocene) sediment have been found to be significantly depleted in ^{13}C compared to phytoplankton markers pointing to a specific origin from alkenones in haptophytes (Grice et al., 1998a), ascribed either to different algal bloom periods of the haptophytes to other algae. D/H of long-chain alkenones have also been used to record freshwater flooding of the eastern Mediterranean during sapropel deposition over the last 10 Myr, with their δD reflecting that of source water and sea surface salinity.

Ciliates

Unusual $\delta^{13}C$ of the biomarker gammacerane can provide information on microbial food sources has been reported. Thus, gammacerane of heterotrophic ciliates feeding on methanotrophic bacteria or archaea can be strongly depleted in ^{13}C (Werne et al., 2002), while gammacerane from ciliates that consume green sulfur bacteria may be enriched in ^{13}C relative to biomass of oxygenic phototrophic organisms (Sinninghe Damsté et al., 1995; Grice et al., 1998d; Santos Neto et al., 1998). Thus, while tetrahymanol occurs in a variety of different organisms, gammacerane derived from bacterivorous ciliates may be recognized by an unusual carbon isotopic composition (Sinninghe Damsté et al., 1995; Werne et al., 2002). Also the carbon isotopic composition of C_{30} 17α , 21β (H) hopane has been found to be similar to gammacerane in certain samples (Grice et al., 1998d) consistent with the notion that C_{30} hopane- 3β -ol occurs together with tetrahymanol in certain bacterivorous marine sauticociliates (Harvey and McManus, 1991).

Terrestrial plants

Long-chain n -alkyl compounds (n -alkanoic acid, n -alkane, and n -alkanol) are key components of epicuticular waxes extracted from the leaves of higher plants (e.g., Eglinton and Hamilton, 1967). Such compounds are ubiquitous found in soils, sediments, atmospheric dust, petroleum, and coal samples. CSIA $^{13}C/^{12}C$ of n -alkyl compounds have been determined in many geochemical studies (Freeman et al., 1990; Hayes et al., 1990), to

establish vegetation inputs. For example, vegetation source assessments (C3 and C4) based on $^{13}C/^{12}C$ of n -alkyl compounds has been widely applied to soils (e.g., Lichtfouse, 1995; Lichtfouse, 1997; Lichtfouse, 1998; Conte et al., 2003; Wiesenberg et al., 2004; Quénéa et al., 2006), marine and terrestrial sediments (Ficken et al., 1998; Huang et al., 2000; Zhao et al., 2000; Schefuß et al., 2003; Zhao et al., 2003; Feakins et al., 2005; and Huang et al., 2006), and atmospheric dust particles (Simoneit, 1997; Huang et al., 2000; and Conte et al., 2003). More recently, CSIA D/H of n -alkyl compounds in geological samples has become an important proxy for paleohydrological cycles (Xie et al., 2000; Andersen et al., 2001; Sauer et al., 2001; Huang et al., 2002; Grice et al., 2003; Yang and Huang, 2003; Dawson et al., 2004; Sachse et al., 2004; Xie et al., 2004; Liu and Huang, 2005; Hou et al., 2006; Smith and Freeman, 2006; Sachse et al., 2006; Sessions, 2006; Pagani et al., 2006; Grice et al., 2008c; Zhou et al., 2010).

It is generally accepted that n -alkyl compounds show $\delta^{13}C$ in the $-35 \pm 5\text{‰}$ range for C3 plants and $-20 \pm 5\text{‰}$ range for C4 plants. A significant difference in $\delta^{13}C$ also exists between C3 angiosperm and gymnosperm, where angiosperm biomass is ^{13}C depleted compared to gymnosperm biomass by ca. 5‰ (Chikaraishi et al., 2004b). δD of n -alkyl compounds are quite similar for all types of higher plants, spanning a range of -250 to -100‰ . Terrestrial plants are more exposed to the external environment, and use water produced by the complex hydrological cycle. An additional source of isotopic fractionation associated with terrestrial plants is evapotranspiration, which leads to the evaporative loss of the light isotopic species of water on leaf surfaces, resulting in an enrichment of D in the remaining water (Dongmann et al., 1974; Liu and Huang, 2005; Smith and Freeman, 2006; Sachse et al., 2006). Several studies on biosynthetic isotopic fractionation during photosynthesis and production of n -alkyl compounds have been carried out (Sessions et al., 1999; Hayes, 2001; Grice et al., 2003; Chikaraishi et al., 2004a, b; Sessions, 2006; Chikaraishi and Naraoka, 2006). The small differences in δD for various lipids reported between different plant types are mainly attributed to variations in physiology (e.g., Smith and Freeman, 2006). In general, terrestrially derived organic matter has been shown to display a wide variation in δD (e.g., Schimmelmann et al., 2004; Xiong et al., 2005). While temperature, humidity, and latitude (Xie et al., 2000; Xie et al., 2004; Pagani et al., 2006) are the most important determining factors, the D/H of meteoric waters in the terrestrial hydrological cycle are also affected by altitude and continentality (e.g., Dawson et al., 2004). These effects are highly changeable, leading to the large isotopic variations observed in terrigenous organic matter. Schimmelmann et al. (2004) measured the δD of the individual fractions of 75 terrestrially derived crude oils and found that the δ values of saturated fractions covered a range from -245 to -62‰ . Xiong et al. (2005) determined the δD of individual n -alkanes in terrestrial Chinese

source rocks from the Turpan and Liaohe Basins, which covered a range from -250 to -140 ‰. Furthermore, the bulk δD of saturated hydrocarbon fractions of marine-evaporitic, lacustrine, and mixed oils reported by Santos Neto and Hayes (1999) showed that the lacustrine oils were enriched in D (by 10–26‰) relative to other oils in the basin.

$\delta^{13}C$ and δD of leaf waxes depends on understanding the relative contribution and isotopic signatures of angiosperm and conifer plants in the rock record, due to the variable isotopic fractionation of CO_2 and water associated with differences in their stomatal structure (Smith et al., 2007). In a study by Pedentchouk et al. (2008) $\delta^{13}C$ and δD compositions of n - C_{27} alkane data were consistent with a lower stomatal conductance for CO_2 and water vapor in conifers relative to angiosperms.

Few studies have focused on $\delta^{13}C$ of aromatic components derived from land plants. In torbanite deposits, alkyphenanthrenes were found to have similar $\delta^{13}C$ to the higher-plant biomarker retene in the same samples (Grice et al., 2001) consistent with a land plant origin for these (e.g., Simoneit, 1997; Alexander et al., 1987, 1988). The proposed mechanism of formation involves rearrangement of phyllocladane precursors yielding 1-methylphenanthrene and retene (Simoneit, 1997; Alexander et al., 1987). The reported isotopic data for retene and alkyphenanthrenes are consistent with a 6 β (H)-phyllocladane (ca. -23 ‰) source also reported in Australian Gippsland Basin oils and close to the average for class I conifer resinites reported by Murray et al. (1998). 1,7-dimethylphenanthrene in the torbanites is thought to be derived from a different precursor, being slightly more depleted in ^{13}C compared with retene possibly deriving from a pimarane type precursor. A multidisciplinary study using molecular and organic isotope geochemistry, petrology, and palynology have been used to establish palaeoenvironmental conditions of fluvio-deltaic deposits from the Delambre-1 well, Western Australia (Triassic–Jurassic) (Grice et al., 2005b). The $\delta^{13}C$ of retene ranging from -26.9 to -24.9 ‰ was also consistent with a source resinite from class I conifers (Murray et al., 1998) and was related to samples rich in Araucariacian conifers.

δD analyses have also been extended to diterpenoid hydrocarbons from land plants in coal and carbonaceous mudstone samples from the Liaohe Basin, China (Tuo et al., 2006). δD for a majority of the n -alkanes range from -150 to -220 ‰. Pristane is reported to be 34–69‰ depleted in D relative to phytane. Diterpenoid hydrocarbons were found to be also depleted in D relative to the n -alkanes indicating a different source for these compounds, although hydrogen exchange could not be fully excluded as a result of thermal maturity (see above). $\delta^{13}C$ of terpenoid hydrocarbons (-24.5 ‰) in samples from the Middle Miocene second Lusatian lignite seam (Lubstów open cast mine, Poland) are attributed fossil wood fragments of gymnosperms (most probably

a species of the coniferales families Taxodiaceae/Cupressaceae) (Bechtel et al., 2007).

Archaea

Marine crenarchaeota

Based on the carbon isotopic composition of kerogen and archaeal lipids, Kuypers et al. (2001) estimated that the dead biomass of marine Crenarchaeota and possibly other Archaea constitutes up to 80% of sedimentary organic matter deposited during the Cretaceous Oceanic Anoxic Event (OAE1b event). The unusually heavy carbon isotopic composition (10‰ vs. PDB) of archaeal lipids suggests that the marine Crenarchaeota had a chemoautotrophic metabolism.

Halophilic archaea

The C_{21} to C_{25} regular isoprenoids extracted from Dead Sea halite deposits (Miocene/Pliocene) were reported to be 7‰ enriched in ^{13}C relative to lipids from phototrophic organisms (Grice et al., 1998d), consistent with the heterotrophic metabolism of Halobacteriales. In the Dead Sea today, *Dunaliella* sp. is the main primary producer and Halobacteriales feed off their biosynthetic products, such as glycerol (Oren, 1993). It is suggested that *Dunaliella*, capable of growing rapidly under hypersaline conditions, may be responsible for producing isotopically heavy products. The consumption of this isotopically heavy glycerol by Halobacteriales would in turn lead to a ^{13}C enrichment of their biomass (Grice et al., 1998d and references therein).

Andersen et al. (2001) reported δD of n -alkanes and isoprenoids attributed to rapid climatic changes during the Messinian salinity crisis, their isotopic data showing that enrichment in D followed climatically driven hydrologic changes in response to intense evaporation.

Sources of methane

Methane can be biogenically produced from CO_2 and H_2 , acetate, or methylated compounds such as trimethylamine and dimethylsulfide (Galimov, 2006 for a review). In marine sediments methane is produced almost entirely via CO_2 reduction via microbes. In terrestrial settings (e.g., freshwater, marsh) acetate fermentation prevails. It has been well-established that methane produced in anaerobic settings is extremely depleted in the ^{13}C . $\delta^{13}C$ of -60 ‰ upward are characteristic of microbial-produced methane (Games and Hayes, 1978). Cross plots of $\delta^{13}C$ and δD measurements (Schoell, 1980; Galimov and Kvenvolden, 1983; Woltemate et al., 1984; Whiticar et al., 1986) are used to establish (a) CO_2 reduction (b) Acetate fermentation pathway. Isotopic shifts have been reported in methane evolved in both freshwater ($\delta^{13}C$ ca. -55 ‰ to -90 ‰) and marine ($\delta^{13}C$ ca. -40 ‰ to -55 ‰) environments (Whiticar et al., 1986). As a result of such fractionations, organisms utilizing isotopically light methane are typically highly depleted in ^{13}C (Summons et al., 1994).

Methanogenic archaea and methane oxidizing archaea

Due to their isotopically light carbon source, lipids of methanotrophic and methane-oxidizing archaea and euryarchaea are commonly characterized by very negative carbon isotopic values. Biomarkers of these organisms include, phytane, 2,6,10,15,19-pentamethylcosane (PMI), crocetane, archaeol, biphytane, hydroxyarchaeol, acyclic biphytanic diacids, and various macrocyclic diphytanyl glycerol diethers (Birgel et al., 2006; Birgel and Peckmann, 2008). Biphytane has also been reported to be enriched in ^{13}C compared to phytoplankton biomarkers by about 4–5‰ in pelagic sediments and in the water column (Hoefs et al., 1997). This difference was ascribed to either (1) the use of dissolved inorganic carbon as carbon source, but with biosynthetic pathways within methanogens discriminating less against ^{13}C than phytoplankton, or (2) archaea obtaining their carbon source from low-molecular weight organic substrates (acetate/methylated amines) generated during decomposition of algal-derived particulate or dissolved organic matter. The methane produced by methanogens is isotopically light compared to their bulk biomass. $\delta^{13}\text{C}$ of PMI in some black shales (Cretaceous) has been found to share a similar $\delta^{13}\text{C}$ to phytane (Vinke et al., 1998). However, other presumed algal biomarkers were in fact lighter by about 10‰, indicating that phytane is probably related to the same source as PMI (an archaeal origin).

The anaerobic oxidation of methane (AOM) with sulfate is the most significant sink for methane in marine settings (Niemann and Elvert, 2008). This process is performed by a consortium of methanotrophic archaea and sulfate reducing bacteria (e.g., Hinrichs et al., 1999; Boetius et al., 2000; Orphan et al., 2001; Reitner et al., 2005; Birgel and Peckmann, 2008).

AOM accounts for an increase in alkaline conditions, causing subsequent precipitation of authigenic carbonates (Ritger et al., 1987; Aloisi et al., 2002). In modern seep environments, biomarkers and their $\delta^{13}\text{C}$ have provided detailed information on microbial activity related to seeps. ^{13}C -depleted archaeal biomarkers reported in limestones associated with ancient methane seeps have linked AOM back Jurassic times (Peckmann et al., 1999; Peckmann and Thiel, 2004; Birgel et al., 2006). Markers of sulfate-reducing bacteria (*iso*- C_{15} -fatty acids and *anteiso*- C_{15} -fatty acids) are characterized by very negative carbon isotopic values (Birgel and Peckmann, 2008).

Coolen et al. (2004) reported lipids of methanogenic archaea and ^{13}C depleted $\Delta^{8(14)}$ sterols supporting an active methane cycle in Ace Lake during the last 3,000 years; extant methanotrophs existed when it became a marine inlet.

Methane oxidizing bacteria

The isotopically light methane produced by methanogenic archaea (above) can be further fractionated by

methanotrophic bacteria leading to biomass becoming depleted in ^{13}C (ca. –90‰) and their sedimentary hopanoid analogues are similarly highly depleted in ^{13}C (Freeman et al., 1990). The presence of ^{13}C -depleted hopanoids in non-marine sediments has been related to bacterial methane cycling in the Messel Shale of Eocene age (ca. –65‰; Freeman et al., 1990), the Green River Formation (ca. –80‰; Collister et al., 1992) and in a recent lake sediment (ca. –50‰; Spooner et al., 1994). Methanotrophic bacteria are probably the major source of 3 β -methylhopanes in sedimentary rocks and oils, as these biomarkers may show a pronounced depletion in ^{13}C compared to co-occurring compounds (see Chapter *Biomarkers (Organic, Compound-Specific Isotopes)*) (Collister et al., 1992; Jahnke et al., 1999).

Apart from ^{13}C depleted isoprenoids derived from methanotrophic archaea, ^{13}C depleted triterpenoids (3 β -methylated hopanoids, $\delta^{13}\text{C}$ –100‰; lanostanes, $\delta^{13}\text{C}$ –80 to –70‰) have also been reported from a number of ancient seep deposits (Birgel and Peckmann, 2008). These data are consistent with contributions of ^{13}C depleted lipids from aerobic methanotrophic bacteria.

Cyanobacteria

Monomethyl and dimethyl branched alkanes, in particular 7-methylheptadecane, 8-methylheptadecane, and 7,11-dimethylheptadecane are known to be biosynthesized by cyanobacteria (e.g., Summons et al., 1998). For example, it has been reported by Summons et al. (1998) that cyanobacteria are able to synthesize normal or branched alkanes of different $\delta^{13}\text{C}$ compositions depending upon the environmental conditions. Cyanobacteria also biosynthesize extended bacteriohopanetetrol derivatives. $\delta^{13}\text{C}$ of extended hopanoids (> C_{30}) determined in sediments (Grice et al., 1996b, 1997; Schouten et al., 1997) generally have similar $\delta^{13}\text{C}$ to algal-derived cholestane and/or phytane, indicating a possible origin from cyanobacteria inhabiting upper regions of a water column. However, Schoell et al. (1994) found $\delta^{13}\text{C}$ differences between the cyanobacterial hopanoids (–29.5 to –31.5‰) and algal-derived steranes (–25‰) in the Middle Miocene which were interpreted as marking the interglacial–glacial transition from a well-mixed to a highly thermally stratified ocean. Schoell et al. (1994) attributed these isotopic differences to cyanobacteria living in deeper parts of the water column of a stratified oceanic environment utilizing a more depleted inorganic carbon source than the algae inhabiting the upper water column. Sinninghe Damsté, et al. (2001) identified two novel glycolipids, docosanyl 3-*O*-methyl- α -rhamnopyranoside and docosanyl 3-*O*-methylxylopyranoside in Ace Lake from Antarctica. $\delta^{13}\text{C}$ measurements showed that the sugar moieties of these glycolipids were ca. 8–9‰ enriched relative to the alkyl chains. Since structurally similar glycolipids have been reported to occur in nitrogen-fixing cyanobacteria, a cyanobacterial origin is proposed for these glycolipids.

Based on empirical isotopic relationships between the tetrapyrrole nuclei of chlorophylls and photoautotrophic cells, it has been concluded that diazotrophic cyanobacteria were the dominant components of phytoplankton communities during the mid-Cretaceous oceanic anoxic events (OAEs) in the western Tethys Sea (Kashiyama et al., 2007). N_2 -fixation was an important and major process in phytoplankton production during these OAEs.

Conclusion

Molecular carbon and hydrogen isotopic compositions of organic matter determined using irm-GCMS, provide significantly more useful information on palaeoenvironments than one gains from $\delta^{13}C$ bulk data. The groundbreaking research into CSIA of biomarkers in geochemistry research has further led to applications in a multiple of microbiological, environmental, medical, geochemical, ecological or biochemical, and forensic research areas. Future areas of interest lie in radiocarbon measurements at the molecular level and the complexity of the N_2 fixation processes in our oceans.

BIOMINING (MINERAL BIOLEACHING, MINERAL BIOOXIDATION)

Douglas Eric Rawlings
 University of Stellenbosch, Matieland, South Africa

Summary

Biomining is the use of autotrophic, acidophilic, iron-, and sulfur-oxidizing microorganisms to produce ferric iron and sulfuric acid. These chemicals are capable of oxidizing a variety of minerals containing insoluble metal sulfides such as Fe₂S, CuS, NiS, and ZnS into their soluble sulfate forms e.g., Fe₂SO₄, CuSO₄, NiSO₄, and ZnSO₄, respectively, resulting in their extraction into water from which they may be more easily recovered. Metal leaching is carried out from mineral waste dumps, or more typically and especially from constructed heap or stirred tank reactors. The metals recovered commercially in the greatest quantities are copper and gold.

Description of the terms bioleaching, biooxidation, and biomining

The term *bioleaching* refers to the conversion of an insoluble metal (usually a metal sulfide, e.g., CuS, NiS, ZnS) into a soluble form (usually the metal sulfate, e.g., CuSO₄, NiSO₄, ZnSO₄). As the metal is extracted into water, this process is called bioleaching. Because this process involves oxidation, it may also be termed *biooxidation*. However, the term biooxidation usually refers to processes in which the recovery of a metal is enhanced by microbial decomposition of the mineral, but the metal being recovered is not solubilized. An example is the recovery of gold from arsenopyrite ores where the gold remains in the mineral after biooxidation and is extracted by cyanide in a subsequent step. The term bioleaching is clearly inappropriate when referring to gold recovery (although arsenic, iron, and sulfur are bioleached from

the mineral). *Biomining* is a general term that may be used to refer to both processes (Rawlings, 2002).

Definition

Biomining is a generic term that refers to a collection of biotechnological processes in which microorganisms are used in the recovery of metals from mineral ores and concentrates. The microbial processes involved are the same as those responsible for acid mine drainage, and where metals are recovered during the treatment of acid mine drainage such a process may be termed biomining. Although the bioadsorption of metals onto biological materials including microorganisms may be used in metal recovery, the term biomining has not been applied to bioadsorption processes.

Metals that are recovered in the greatest quantities in commercial processes are copper, gold, and cobalt. Illustrations of the number and scale of operations that employ microorganisms for metal recovery are to be found in Olsen et al. (2003) and Rawlings et al. (2003). Processes also exist for the treatment of nickel- and zinc-containing ores although recovery of these metals using "biomining" has not been commercialized. For several years uranium was recovered using related processes (McCready, 1988) and the technology has the potential for the recovery of several other types of metals. In general, to be amenable to biologically assisted leaching, the mineral should contain iron or a reduced form of sulfur.

Biomining processes use the action of microbes for one of two purposes (Rawlings, 2005). Either to convert insoluble metal sulfides (or oxides) to water soluble metal sulfates or as a pretreatment process to open up the structure of the mineral thereby permitting other chemicals to better penetrate the mineral and solubilize the desired metal. An example of the first type of process is the conversion of insoluble copper present in minerals such as covellite (CuS) or chalcocite (Cu_2S) to soluble copper sulfate. An example of the second is the removal of iron, arsenic, and sulfur from gold-bearing arsenopyrite so that the gold that remains in the mineral is more easily extracted by subsequent treatment with cyanide. Both are oxidation processes, but when the metal to be recovered is extracted into solution, the process is known as bioleaching, whereas when the metal remains in the mineral, bioleaching is an inappropriate term and the process should strictly be referred to as biooxidation. The term bioleaching is frequently used for both.

Mechanisms of biologically assisted leaching

Current understanding is that biooxidation is primarily a chemical process. Sand and coworkers have proposed that minerals can be divided into two broad categories, acid-insoluble minerals that are solubilized through oxidation by ferric iron (e.g., FeS_2 , MoS_2 , and WS_2) and acid-soluble minerals that are oxidized by the combined action of ferric iron and protons (e.g., ZnS , PbS , FeAsS , CuFeS_2 ,

and MnS_2). The role of the microorganisms is to provide the ferric iron and sulfuric acid leaching agents. Leaching reactions have been presented in Schippers and Sand (1999) and Rohwerder et al. (2003) and are reviewed in Rawlings (2005).

Because bioleaching processes are chemistry-driven, if a mineral (such as chalcopyrite) is recalcitrant to biooxidation at 40°C , the solution to the problem lies primarily in the realm of chemistry rather than biology. For example, an increase in the temperature of the biooxidation process to 80°C will allow the chemical reactions to take place at a much faster rate. However, the biology needs to follow the chemistry, and microorganisms that are capable of iron and sulfur oxidation at 80°C are required to generate or regenerate the lixiviants (leaching chemicals).

Although it is possible to separate the chemistry of metal solubilization from the biology into two different processes, separation is unlikely to be as efficient as when both processes are carried out together. The reason for this is that the role of the microorganisms is considered to be more than the generation of the ferric iron and acid required for the chemistry of mineral biooxidation. Contact between the microbes and the mineral is important (though not essential) because the microorganisms produce an exopolysaccharide layer when attached to a mineral (Sand et al., 1995). This layer serves as a reaction space where mineral dissolution reactions take place more efficiently than in the bulk solution. Increased efficiency is partly because conditions within the exopolysaccharide layer (e.g., concentration of ferric iron, redox potential, and pH) are substantially different and more favorable for leaching compared with conditions in the bulk solution (Rawlings, 2005).

Biomining processes

Heap reactors

Commercial mineral bioleaching can take place using a low technology process such the irrigation of waste ore dumps (Brierley, 1982). The efficiency of metal recovery may be improved by the construction and irrigation of specially designed heaps rather than by the irrigation of an existing, nonengineered dump (Brierley, 1982; Rawlings et al., 2003). During heap construction, agglomerated ore is piled onto an impermeable base and supplied with an efficient leach liquor distribution and collection system. Acidic leaching solution is percolated through the crushed ore, and microbes growing on the surface of the mineral in the heap produce the ferric iron and acid that carry out mineral dissolution and metal solubilization. Good aeration enhances the metal leaching reaction. Aeration can be passive, with air being drawn into the reactor as a result of the flow of liquid or may be active with air blown into the heap through piping installed near the bottom. Metal-containing leach solutions that drain from the heap are collected and sent for metal recovery. Heap reactors can be of enormous size (Rawlings et al., 2003), are

relatively cheap to construct and operate, and are therefore suited to the treatment of lower grade ores. Compared with tank reactors, the metal recovery efficiency of heap reactors tends to be low. Heap reactors are more difficult to aerate efficiently and undesirable gradients of pH, nutrients, and liquor channeling are difficult to manage. In addition, although initial rates of bioleaching can be improved by effective heap inoculation, it is difficult to achieve in practice and nondeliberate inoculation that occurs during irrigation may be the main method by which microorganisms are spread through a heap.

Tank reactors

Continuous-flow stirred tank reactors placed in series are used to treat high-value finely milled mineral concentrate or ore. Such tanks can be of considerable size, for example, the 1,300 m³ tanks used to process cobalt-containing pyrite at Kasere, Uganda. Mineral concentrate is added to the first tank, together with inexpensive inorganic nutrients in the form of ammonia- and phosphate-containing fertilizers. The mineral suspension flows through the series of highly aerated tanks that are pH- (typically pH 1.5–1.6) and temperature-controlled. Stirred tank reactors that operate at 40°C and 50°C have proven to be highly robust, and very little process adaptation is required for the treatment of different mineral types. Mineral solubilization takes place in days rather than the weeks or months required in heap reactors. A constraint on the operation of stirred tank reactors is the quantity of solids (pulp density) that can be maintained in suspension, which is limited to about 20%. At pulp densities >20%, physical mixing and microbial problems occur. The liquid becomes too thick for efficient gas transfer and the shear force induced by the impellers cause physical damage to the microbial cells. The limitation in solids concentration together with higher capital and running costs has restricted the use of stirred reactors to high value minerals or mineral concentrates. Stirred tanks are used as a pretreatment process for gold-containing arsenopyrite concentrates, with the first of these having been built at the Fairview mine, Barberton, South Africa in 1986. The largest stirred tank process is at Sansu in the Ashanti goldfields of Ghana, West Africa, where 960 tonnes of gold concentrate are processed per day.

Types of microorganisms

Both heap and tank biooxidation processes contain a variety of microorganisms, with two different organisms usually dominating: an iron-oxidizer and a sulfur-oxidizer. A wide variety of these microorganisms may be present (Rawlings and Johnson, 2007). Irrespective of the type of process or temperature, these microbes have several features in common that make them suitable for their role in mineral dissolution. They grow autotrophically by fixing CO₂ from the atmosphere which makes it unnecessary to provide them with a fixed carbon source. Their energy is obtained by using either ferrous iron or reduced

inorganic sulfur compounds (some use both) as electron donors. Oxygen is generally used as the electron acceptor. All are acidophiles and grow in low-pH environments (pH 1.4–1.6 is typical) and they tend to be tolerant of a wide range of metal ions (Dopson et al., 2003). These very modest nutritional requirements can generally be met by the aeration of the iron- and/or sulfur-containing mineral suspension in water or the irrigation of a heap. Small quantities of inorganic fertilizer may be added to ensure that nitrogen, phosphate, potassium, and trace element limitation does not occur.

The types of organisms found in heap and tank reactors that operate at different temperatures have been reviewed (Rawlings and Johnson, 2007). In general, bacteria belonging to the genera *Acidithiobacillus* and *Leptospirillum* tend to dominate the processes up to 40°C, with those belonging to the genera *Acidithiobacillus*, *Leptospirillum* and *Sulfobacillus* dominating the processes between 45 and 55°C. In high-temperature processes (60–80°C), archaea such as *Acidianus*, *Metallosphaera*, and *Sulfolobus* are responsible for iron- and sulfur-oxidation rather than bacteria.

Definition

Active or passive microbially induced or mediated consolidation, cleaning, and/or protection of (stone) artworks affected by chemical, physical, and/or biological weathering phenomena. Bioprotection includes the microbially mediated removal (cleaning) of deleterious compounds (sulfates, nitrates, and/or organics), and the in situ cementation (consolidation) of ornamental materials via microbially induced biomineralization. Bioprotection also occurs naturally on rock surfaces where microorganisms aid in the formation of cementing phases such as oxalates and carbonates, and biofilms.

Introduction

The term bioprotection has been applied to a range of processes and applications involving microorganisms. They include microbe-induced defense response in plant–soil interactions, plant/crop treatment, food processing, and toxic metal decontamination (Glazer and Nikaido, 2007), prevention of wood decay (Dawson-Andoh and Morrell, 1992), inhibition of steel corrosion (Volkland et al., 2000), natural protection of rock outcrops (Carter and Viles, 2005) and building stones (Di Bonaventura et al., 1999), as well as cultural heritage conservation (Ciferri et al., 2000; Rodriguez-Navarro et al., 2003; Ramirez et al., 2005; Webster and May, 2006). Here, the term bioprotection refers both to the use of microorganisms (mainly bacteria) for the conservation of stone artworks, and to the microbially mediated formation of natural protection layers on rock outcrops and stone surfaces. Such meanings are the most commonly used and accepted in

geobiology, as they involve the interaction between the biosphere and the geosphere.

Although “carved in stone” is meant to be durable or eternal, ornamental stones are subjected to a range of physical, chemical, and biological weathering phenomena that lead to their eventual crumbling and disintegration. Such weathering processes have been exacerbated by anthropogenic emission of pollutants since the Industrial Revolution (Winkler, 1994). As a consequence, stone monuments and statuary are at risk worldwide.

Granites, sandstones, and carbonate rocks – limestone, dolostone, and marble – are among the most common stones used in monuments and statuary. Carbonate stones, made up of calcite (CaCO_3) and/or dolomite ($\text{CaMg}(\text{CO}_3)_2$), are particularly prone to chemical weathering in polluted (urban) environments, as exemplified by the decay of the Parthenon or the Taj Mahal. Wet (acid rain) and dry deposition of atmospheric pollutants contribute to the leaching of these sparingly soluble carbonates and the formation of sulfate – gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) – crusts, also named “black crusts” (Figure 1). Carbonate stones are also prone to physical–mechanical weathering associated to salt crystallization, insolation weathering, frost damage, and hydric expansion/contraction (Winkler, 1994; Gauri and Bandyopadhyay, 1999; Rodriguez-Navarro et al., 2003). Biodeterioration is also a major

Bioprotection, Figure 1 Black crusts developed on a limestone gargoyle at the Royal Chapel, Granada (Spain).

contributor to the decay of stones in general, and carbonate stones in particular (McNamara and Mitchell, 2005).

Conservation of decayed stoneworks typically involves cleaning (by mechanical or chemical means) and/or protection/consolidation. Organic (e.g., acrylic or epoxy resins), organo-inorganic (e.g., ethyl silicates), and inorganic (e.g., $\text{Ba}(\text{OH})_2$ and $\text{Ca}(\text{OH})_2$ solutions) protection/consolidation treatments have been applied in the past to alter or mitigate stone decay (Lazzarini and Tabasso, 1986; Price, 1996). However, none of these treatments have been proven to be satisfactory (see Rodriguez-Navarro et al., 2003 and references therein). The limitations and drawbacks of these “classic” conservation treatments have prompted the search for new methods to clean, protect and consolidate weathered ornamental stones. One promising line of research has focused on microbial bioprotection as a new means for the restoration and consolidation of ornamental stone.

Microbial-stone interactions: biodeterioration versus bioprotection

It has been known for decades that microbes actively contribute to the degradation of ornamental stone (McNamara and Mitchell, 2005). For instance, the metabolic activity of nitrifying bacteria (*Nitrosomonas* sp. and *Nitrobacter* sp.) results in the production of nitric acid, which in turn causes dissolution of stone and formation of deleterious nitrate salts (Fernandez, 2006). Sulfur-oxidizing bacteria such as *Thiobacillus* sp. produce sulfuric acid and contribute to the development of sulfate crusts (Warscheid and Braams, 2000). Biofilms can exacerbate microbial biodeterioration as they provide a shelter for the aforementioned bacteria, and act as a reservoir for nutrient storage (McNamara and Mitchell, 2005). Wetting and drying of the biofilm matrix may lead to swelling/shrinking of the extracellular polymeric substances (EPS), causing mechanical damage to the host stone (Warscheid and Braams, 2000).

Although microbes are often the problem, they can also be the solution (Rinaldi, 2006). For instance, the anaerobic sulfate-reducing bacteria *Desulfovibrio desulfuricans* and *D. vulgaris* have been shown to be effective for the removal of gypsum crusts (Webster and May, 2006; Cappitelli et al., 2007). Similarly, nitrate salts can be eliminated through the application of nitrate-reducing bacterial cultures (Fernandez, 2006), while *Pseudomonas stutzeri* has been successfully applied to eliminate organic residues from frescoes (Ranalli et al., 2005).

There is growing evidence that several microorganisms contribute to the natural bioprotection of rock outcrops (Carter and Viles, 2005) as well as ornamental stone (Di Bonaventura et al., 1999) via the formation of biofilms and cemented surface layers. Some bacterial communities can promote the production of protective calcium oxalates on building stone (Di Bonaventura et al., 1999), or inhibit calcite dissolution (Rinaldi, 2006). Numerous strains of

bacteria isolated on different building stones are able to induce the precipitation of calcium carbonate (Urzi et al., 1999), an effect that may have aided in the natural protection of weathered ornamental stones. This latter ability has opened new ways for the effective protection and consolidation of decayed ornamental stones based on the in situ mineralization of bacterial carbonate cement (Rodriguez-Navarro et al., 2003; Webster and May, 2006; Jimenez-Lopez et al., 2007).

Bacterially mediated biomineralization of carbonates

The precipitation of carbonate minerals mediated or induced by both autotrophic and heterotrophic bacteria have attracted a substantial amount of research (see recent review by Wright and Oren, 2005). Bacterial precipitation of calcium carbonate has important implications in the past and present formation of carbonate rocks and sediments (Rodriguez-Navarro et al., 2003; Wright and Oren, 2005). It is known that cyanobacteria have aided in the formation of mineralized stromatolites since the Precambrian age (Konhauser, 2007), their photosynthetic activity thus contributing to atmosphere oxygen increase and CO_2 budgeting by carbonate precipitation. While early work (until the 1980s) examined the ability of photosynthetic bacteria to precipitate calcium carbonates in marine environments, precipitation of carbonates induced by heterotrophic bacteria in other environments such as caves, soils, and monuments has become the subject of much research in recent decades (Boquet et al., 1973; Urzi et al., 1999).

Bacteria play both passive and active roles in carbonate nucleation (Mitchell and Ferris, 2006). In the first case, the metabolic activity of heterotrophic bacteria (e.g., ammonification of amino acids, urea degradation, and dissimilatory reduction of nitrates and sulfates), or photosynthetic HCO_3^- consumption and OH^- production by cyanobacteria, increases the alkalinity (high pH, and elevated CO_3^{2-}) in the microenvironment surrounding the bacterial cells. This in turn increases supersaturation with respect to calcium carbonate if free Ca^{2+} is present, thus favoring calcification. Bacterial cell walls and/or sheets, as well as EPS, can actively aid in carbonate crystallization by providing heterogeneous nucleation sites (Ercole et al., 2007; Rodriguez-Navarro et al., 2007).

Bioprotection of stone by bacterial biomineralization of carbonates

Based on previous work on the natural ability of many heterotrophic bacteria to induce calcium carbonate precipitation, Adolphe et al. (1990) patented a method, CALCITE, for bacterial bioprotection of ornamental stones. The authors showed that calcinogenic bacteria, such as those typically found in soils (Boquet et al., 1973), were able to precipitate calcite on the surface of weathered limestone, thus contributing to their protection and consolidation. Le Métayer-Levrel et al. (1999) reported the

“successful” application of such a method on a sixteenth century limestone castle. Nonetheless, the authors used *Bacillus cereus* cultures, which may pose a health risk. In addition, potentially harmful biofilm formation and only a few micrometers thick consolidated layer were observed. Tiano et al. (1999) evaluated the effectiveness of such a treatment for bioprotection of a highly porous limestone (Pietra de Lecce) using *Micrococcus* sp. and *B. subtilis*. They observed detrimental obstruction of pores (presumably by biofilm formation), and called attention to other potential drawbacks e.g., reaction of the stone and by-products of bacterial activity, and the formation of stain patches. Rodriguez-Navarro et al. (2003) showed that such limitations could be overcome by using different culture media and a non-pathogenic carbonate-producing heterotrophic soil bacteria, *Myxococcus xanthus*. The treatment resulted in deep consolidation of a porous limestone (calcarenite) with new bacterial calcium carbonate cement, without detrimental pore plugging or extensive biofilm formation. *M. xanthus* metabolic activity results in the release of NH_3 , which leads to a pH rise in the medium surrounding the bacterial cells. This in turn favors carbonate supersaturation and results in CaCO_3 precipitation on different calcareous stones such as limestone and marble (Figure 2). Carbonates typically form on the bacterial cell walls, where heterogeneous nucleation is facilitated, and grow as a coherent cement (often epitaxially) on the stone support. Rodriguez-Navarro et al. (2003) also showed that the new bacterial calcite cement was tougher and more resistant to dissolution than the original calcite

in the stone. They interpreted these results considering that organic by-products of bacterial activity were incorporated into the bacterial calcite, which was in fact a (bio) composite material. Interestingly, Ben Chekroun et al. (2004) and Rodriguez-Navarro et al. (2007) showed that *M. xanthus* induced the precipitation of either calcite or vaterite just by modifying the culture medium. These results demonstrate that polymorph selection in carbonate precipitation is not strain specific. On the other hand, recent research using *B. subtilis* (Perito and Mastromei, 2003), *B. sphaericus* and *B. lentus* (Dick et al., 2006) shows that the range of microorganisms that can contribute to the bioprotection of ornamental stone via the precipitation of carbonates is very wide. In addition, it has been shown that bacteria such as *M. xanthus* can precipitate a range of minerals, other than carbonates, just by changing the composition of the culture medium (Ben Chekroun et al., 2004). These results imply that an accurate selection of growth media and bacterial strains could yield improved protection and consolidation of ornamental stones with disparate composition and textures.

Bioprotection treatments based on bacterial biomineralization are not restricted to ornamental stone. Castanier et al. (1996) used *Pseudomonas* sp. for calcite precipitation as a cementing phase in a biological mortar. Bang et al. (2001) have reported that polyurethane-immobilized *B. pasteurii* (a carbonatogenic ureolytic bacteria) can fill the cracks in concrete. Whiffin et al. (2007) have shown that carbonate precipitation induced by *Sporosarcina pasteurii* contributes to soil strengthening.

Bioprotection, Figure 2 Bacterially mediated calcite biomineralization on Macael marble: (a) Severe damage on a Macael marble lion sculpture at the Lions Court, The Alhambra, Granada, Spain; (b) scanning electron microscopy photomicrographs of a Macael marble sample before and (c) after bacterial conservation treatment resulting in *M. xanthus* mediated calcite cement formation.

Summary

Weathered ornamental stones typically contain a variety of endolithic and epilithic microbial communities (Urzi et al., 1999; McNamara and Mitchell, 2005). Application of bacterial treatments that include a nutritive medium may thus activate, among the microbial community contained in the stones, those bacteria that are able to induce the precipitation of calcium carbonate. In this respect, Jimenez-Lopez et al. (2007) have shown that the application of sterile nutritive media to porous limestone is able to activate carbonatogenic bacteria. As a consequence of the growth of these bacteria, an alkalization occurs that results in calcium carbonate precipitation. The new precipitate is compatible with the substrate and consolidates the stone without pore plugging. Such effects are reinforced by the presence of *M. xanthus*. Therefore, a good candidate to in situ consolidate decayed porous limestone is the application of a sterile culture medium with specific characteristics that favor the development of calcinogenic bacteria, while limiting the proliferation of detrimental microbiota (Jimenez-Lopez et al., 2007). Such an alternative to the direct application of life cells is highly promising. Finally, bacterial biomineralization of silicates as a means to consolidate non-carbonate stones such as granite and sandstone is another topic that should be further studied.

BIOSIGNATURES IN ROCKS

Frances Westall, Barbara Cavalazzi
 Université de Orléans, Orléans, France

Definition

Biosignatures are morphological, chemical (organic, elemental and/or mineral), and isotopic traces of organisms preserved in minerals, sediments, and rocks. They represent the physical presence of the organisms as well as evidence of their metabolic activities and metabolites.

The nature of biosignatures

In this entry, we review (1) the nature of biosignatures in rocks, (2) how they are produced, and (3) the relevance of biosignatures and their astrobiological implications. Examples of biosignatures from throughout the rock record are given. We will limit our discussion to microbial biosignatures.

Microorganisms are characterized by (1) structural components, such as cells, colonies, biofilms/mats, extracellular polymeric substances (EPS); (2) the chemical composition of the different structural elements, including organic molecules and other essential elements; and (3) their living processes, including metabolic activity leading to the fractionation of elements such as C, S, O, N, P, and Fe, as well as cell division. Indirectly, microorganisms are also characterized by (4) the effects of their

physical presence and metabolic products on their immediate environment. These effects may be preserved on a microscopic to macroscopic scale. They include the precipitation of minerals; element leaching from, and dissolution of, minerals and rocks (biocorrosion); influence on mineral grain size and habit; the formation of microbially induced sedimentary structures (MISS; cf. Noffke et al., 2003) and biostabilization of sedimentary surfaces; and the formation of microbialites (e.g., microbial mounds, stromatolites, thrombolites) and microbial fabrics (e.g., clots, peloids, fenestrae). All of these phenomena can leave morphological, chemical, or isotopic traces in rocks (Table 1), but do not always do so. The ultimate fate of biosignatures is dependent upon their immediate preservation and the history of the sediments and rocks during subsequent diagenesis, metamorphism, and weathering.

The various types of biosignatures are discussed in detail elsewhere in this volume. Our aim here is to provide a brief overview of the broad range of biosignatures in rocks and to discuss their relevance and astrobiological implications.

Biosignatures of cell components and metabolic activity

Fossil carbon molecules

All terrestrial life consists of assemblages of macromolecules based on carbon (with water as the universal solvent, Brack, 2002) and the different components of the cell, i.e., cytoplasm, chromosomes, chloroplast, and cell walls and envelopes, etc., are characterized by molecules of different composition and structure. Molecular degradation starts with the death of the organism and may also be aided by the activity of other microorganisms, e.g., the heterotrophs, who obtain their energy and carbon from the breakdown of organic substances. The chemical changes that take place during degradation (diagenesis) are dependent on the redox state and water chemistry of the environment. Degradation of macromolecules to form “fossil” molecules results in the gradual loss of the functional groups. Specific characteristics of fossil molecules that suggest a biological origin include (1) enantiomeric excess (chirality), (2) diastereoisomeric preference, (3) structural isomer preference, (4) repeating constitutional subunits or atomic ratios, (5) systematic isotopic ordering at molecular and intramolecular levels, and (6) uneven distribution patterns or clusters, such as C-number, concentration, or $\delta^{13}\text{C}$, of structurally related compounds (Summons et al., 2008).

Preservation of fossil molecules

Fossil organic molecules or biomarkers are best preserved in anaerobic environments where they are protected from abiotic oxidation or aerobic microbial degradation. Subsequent burial, metamorphism, and heat events (e.g., hydrothermal/volcanic activity) affect the “maturity” or degradation state of the organic matter. This results in the formation of different types of kerogen characterized

Biosignatures in Rocks, Table 1 Morphological, chemical, and isotopic biosignatures in rocks

Major microbial components	Biosignature	Specific component or structure	
Cell components	Organic molecules (biomarkers, kerogen)	Composition chemical structure	Odd/even C number μ -structure
Cell metabolic activity	Biominerals	Direct (e.g., magnetite) indirect (e.g., microcrystalline calcite, aragonite, dolomite)	
	Elements	Concentration Isotopic ratios	e.g., Ni, Cu, Mn, Co, Mo, Se, V, Fe e.g., C, O, S, N, Fe
	Microbial influence on:	Mineral composition, mineral habit, mineral dissolution, mineral size	
Cell colonies, biofilms, mats, EPS	Fossil cells, colonies, mats	Clotted fabrics, microbial mounds, biolaminites	Stromatolites MISS ^a

by H/C ratios ranging from >1.25 for Type I kerogen to <0.5 for type IV kerogen. The small molecular size of some of the degraded molecules means that they are readily mobile and can be transported into other formations with which they are not syngenetic, thus causing contamination. The oldest known biomarkers occur in carbonaceous oil shales from the 2.7 Ga-old Fortescue Group in Australia where molecules such as hopanes and steranes, the degradation products of prokaryotes (specifically aerobic photosynthesizers, cyanobacteria) and eukaryotes, respectively, were interpreted as evidence for oxygenic photosynthetic activity by 2.7 Ga (Brocks et al., 1999) and, more importantly, the early rise of eukaryotes (Summons et al., 1999). These biomarkers have, however, recently given rise to controversy regarding their syngeneticity (Eigenbrode and Freeman, 2006; Rasmussen et al., 2008).

Syngenetic organic molecules occur in even older sediments but the kerogens in the volcanic sediments in the 3.5–3.3 Ga-old Barberton (South Africa) and Pilbara (Australia) greenstone belts are so degraded by age and low-grade metamorphism (prehnite–pumpellyite to lowest greenschist facies) that they no longer contain recognizable compositional biomarkers. The kerogens do, however, retain structural characteristics that are indicative of a biological origin (Westall et al., 2006a; Derenne et al., 2008). Evidence of syngeneticity of the kerogens analyzed is provided by in situ Raman spectra showing D and G peaks indicative of a maturity consistent with the metamorphic grade of the rocks (Westall et al., 2006a), as well as covalent linking of the molecular structures in the kerogen matrix (Derenne et al., 2008).

Traces of cell metabolism and metabolites

The metabolic activity of microorganisms can result in elemental, isotopic, and mineral signatures that can be preserved in rocks.

Bioelements: Unusual concentrations of metals may be associated with microorganisms and their metabolic products. Adsorption of these elements may be either an active or a passive process. Active adsorption includes the chelation of metals to anionic functional groups in the cell walls to neutralize their negative charges, thus contributing to the stability of the cell wall. Microorganisms also require metals, such as Fe, Co, Ni, Cu, Mn, Mo, Se, and V, for certain enzymatic activities (Banfield et al., 2001). They are actively adsorbed onto the cell walls by ligands that are specific for a particular metal (Konhauser, 2007). Microorganisms can also concentrate toxic elements, such as U, Cu, Pb, Al, As, and Cd, as well as precious metals (U, Cu, Pd, Pt, and Au) that are bound to cells and S-layers (Pollmann et al., 2006).

Passive adsorption of metal ions to cell surfaces is an additional kind of metal sequestration (Ledin, 1999). The availability of functional molecules, such as carboxyl or phosphate groups, determines the amount of metals that can be sorbed to the cell surface. With their large quantities of peptidoglycan, Gram positive bacteria can readily scavenge metal ions. Gram negative bacteria, on the other hand, are characterized by only a thin layer of peptidoglycan sandwiched between an outer lipopolysaccharide layer and an inner phospholipid layer. The amount of metal that they can bind is an order of magnitude less than that of the Gram positive bacteria (e.g., Beveridge et al., 1982). Microbial EPS is also an important factor in the binding of metals owing to their highly hydrated character that allows the metal ions to freely migrate through the structure (Geesey and Jang, 1989). This characteristic means that microorganisms, such as encapsulated bacteria, are more likely to chelate metals than non-encapsulated varieties. Metal-replaced microorganisms are common and are among the oldest traces of life. Fossil microorganisms preserved as pyritized filaments occur in a 3.2 Ga-old volcanogenic

massive sulfide deposit (the equivalent of a fossilized black smoker) from the Pilbara in Australia (Rasmussen, 2000). A younger example consists of ZnS-replaced filaments in Triassic calcareous rocks in the southern Alps (Kucha et al., 2005).

Concentrations of other biologically important elements, such as P and S, are considered to be significant biosignatures. For example, the combination of graphite associated with apatite inclusions (apatite can be a biomineral, cf. Table 2) and a $\delta^{13}\text{C}$ of -26‰ in a highly metamorphosed rock from the 3.85 Ga-old Akilia province in W. Greenland was interpreted as a biosignature by Mojzsis et al. (1996). However, van Zuilen et al. (2002) demonstrated that abiological processes linked to alteration of the rocks by hydrothermal circulation could have produced carbon via the Fischer–Tropsch process with a similar isotopic signature. On the other hand, phosphatized microorganisms are well-known from the rock record. The spectacular preservation of soft body parts of animals, birds, amphibians, and fish from the Eocene Messel oil shales in Germany is due to phosphatized microbial biofilms that coated the dead organisms (Liebig et al., 1996).

High concentrations of sulfur can be found in kerogen owing to the process of sulfurization during which sulfur, liberated from degrading organic matter by the activity of sulfur-reducing bacteria, is bound to the organic macromolecules. Thus, the identification of the S-molecule thiophene in the organic cell walls of microfossils from the

800 My-old Draken Formation of Svalbard (Lemelle et al., 2008) and even in 2.7 Ga-old kerogen associated with stromatolites from the Tumbiana Formation in the Pilbara (Lepot et al., 2008) has been linked to the degradation of organic matter by sulfur-reducing bacteria.

Biominerals: Minerals of different phases can be formed both actively and passively by microorganisms in biologically controlled and biologically induced processes, respectively. Microbially induced mineralization occurs either as a result of changes in the environment of a microorganism caused by the excretion of metabolic waste products, enzymatic mediated changes in the redox state, or simply the presence of a charged cell surface that attracts mineral nucleation (Banfield et al., 2001; Konhauser, 2007). We have seen above that reactive functional group sites on microbial surfaces readily chelate metal ions. In the same way mineral nuclei in saturated solutions bind to the surfaces of cells and their extrapolymeric substances (EPS), often completely entombing the microorganisms. A non-exhaustive list of microbially induced mineral precipitates is given in Table 2.

Iron hydroxides (ferrihydrite) are among the most common microbially induced deposits and may be formed passively, or by the activities of chemoheterotrophic, photoautotrophic, or chemolithoautotrophic (e.g., *Gallionella*) microorganisms. The ferric hydroxides may act as precursors for Fe oxides, such as hematite. Manganese nodules are an example of microbially induced

Biosignatures in Rocks, Table 2 Non-exhaustive list of microbially induced mineral precipitates

Metal oxides	Fe/Mn hydroxides and oxyde-hydroxides (or oxyhydroxides), e.g., ferrihydrite (ferric hydroxide), $\text{Fe}^{3+}_2\text{O}_3 \cdot 0.5(\text{H}_2\text{O})$, goethite, $\text{Fe}^{3+}\text{O}(\text{OH})$, schwertmannite, $\text{Fe}^{3+}_{16}\text{O}_{16}(\text{OH})_{12}(\text{SO}_4)_2$
Amorphous silica	Fe/Mn/Ti oxides, e.g., magnetite, $\text{Fe}^{3+}_2\text{Fe}^{2+}\text{O}_4$, hematite, $\text{Fe}^{3+}_2\text{O}_3$, anatase, TiO_2
Carbonates	Opal, $\text{SiO}_2 \cdot n(\text{H}_2\text{O})$, e.g., opal-A and opal-A/CT
Carbonates	Ca-carbonates, e.g., calcite, $\text{Ca}(\text{CO}_3)$, magnesian calcite, High-/Low-Mg $\text{Ca}(\text{CO}_3)$, aragonite, CaCO_3 , dolomite, $\text{CaMg}(\text{CO}_3)_2$
Carbonates	Magnesite, $\text{Mg}(\text{CO}_3)$
Carbonates	Strontianite, $\text{Sr}(\text{CO}_3)$
Phosphates	Ca-phosphates, e.g., apatite, $\text{Ca}_5(\text{PO}_4)_3(\text{OH}, \text{F}, \text{Cl})$, carbonate-hydroxylapatite, $\text{Ca}_5(\text{PO}_4)_3(\text{OH})$, francolite, or carbonate fluoroapatite, $\text{Ca}_5(\text{PO}_4)_3\text{F}$
Phosphates	Fe-phosphates, e.g., vivianite, $\text{Fe}^{3+}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$
Sulfates	Barite, BaSO_4
Sulfates	Celestine, SrSO_4
Sulfates	Gypsum, $\text{Ca}(\text{SO}_4) \cdot 2(\text{H}_2\text{O})$
Sulfates	Fe-sulfates, e.g., jarosite, $\text{KFe}^{3+}_3(\text{SO}_4)_2(\text{OH})_6$
Sulfides	Chalcopyrite, $\text{CuFe}^{2+}\text{S}_2$
Sulfides	Galena, PbS
Sulfides	Greigite, Fe_3S_4
Sulfides	Mackinawite, FeS
Sulfides	Millerite, NiS
Sulfides	Pearceite, $\text{Ag}_{16}\text{As}_2\text{S}_{11}$
Sulfides	Proustite, Ag_3AsS_3
Sulfides	Pyrite, Fe^{2+}S_2
Sulfides	Sphalerite, $(\text{Zn}, \text{Fe})\text{S}$
Silicates	Clay minerals, e.g., phillipsite, $(\text{Ca}, \text{Na}, \text{K})1-2(\text{Si}, \text{Al})_8\text{O}_{16} \cdot 6(\text{H}_2\text{O})$, chamosite, $(\text{Fe}^{2+}, \text{Mg}, \text{Fe}^{3+})_5\text{Al}(\text{Si}_3\text{Al})\text{O}_{10}(\text{OH}, \text{O})_8$, illite, $(\text{K}, \text{H}_3\text{O})(\text{Al}, \text{Mg}, \text{Fe})_2(\text{Si}, \text{Al})_4\text{O}_{10}[(\text{OH})_2, (\text{H}_2\text{O})]$, smectite $(\text{Na}, \text{Ca})\text{Al}_4(\text{Si}, \text{Al})_8\text{O}_{20}(\text{OH})_4 \cdot 2(\text{H}_2\text{O})$

iron-manganese oxides that can form volumetrically important deposits in the deep-sea and lacustrine environments (Mero, 1962).

Amorphous silica commonly nucleates passively onto the surfaces of microorganisms in hot spring environments (Figure 1a) (e.g., Cady and Farmer, 1996) and precipitates from saturated solutions in other environments as well. For example, Monty et al. (1991) and Westall (1994) documented silicified microorganisms in the pore space of 15–10 My-old deep-sea sediments. At the other end of the geological record, silica-saturated seawaters on the early Earth led to the silicification of early Archaean microbes and the preservation of the oldest known traces of life (Figure 1b) (Walsh, 1992; Westall et al., 2001, 2006a, b; Westall and Southam, 2006).

Perhaps the most geologically significant microbially induced mineral deposits are those related to carbonates. The carbonate minerals are produced by processes including mineralization of microbial surfaces, chemical precipitation from supersaturated solutions, and physical erosion of preexisting carbonates (Riding, 2000). Microbial carbonates occur in a wide variety of environments ranging from deep-water cold seeps (Figure 2) (e.g., Cavalazzi et al., 2007), shallow-water platforms (Figure 3a) (e.g., Monty, 1995), lacustrine environments (Figure 3b and c) (e.g., Laval et al., 2000) to carbonate (travertine) springs (e.g., Chafetz and Folk, 1984).

Biologically controlled mineralization occurs when microorganisms exert direct control on the nucleation and growth of the mineral (Mann, 1988). The resulting minerals are characterized by their highly ordered crystal-line structure, size, and morphology. Chains of single-domain magnetite crystals are formed in this way by magnetotactic bacteria (e.g., Bazylinski et al., 1995) and Chang and Kirschvink (1989) record chains of magnetite crystals in the 1.9 Ga-old Gunflint Formation (Canada) that are similar in size and shape to those produced by

recent bacteria. Indeed, the presence of chemically pure magnetite crystals with a specific size/shape range in an ancient Martian meteorite, ALH84001, is one of the key lines of evidence for life on Mars by 3.9 Ga (McKay et al., 1996; Thomas-Keprta et al., 2001, 2002; Friedmann et al., 2001). However, the supposedly biogenic magnetites form only a fraction (<30%) of a larger population that includes magnetites of clearly abiological origin and it is questioned whether this assemblage is purely fortuitous. Moreover, similar magnetites have been produced in the laboratory by abiogenic processes (Golden et al., 2004).

The presence of microbial metabolites plus the physical presence of the organic components can have an enormous effect on the elemental composition and dissolution of minerals, as well as the shape and size of the crystals. Microbial dissolution of nonorganic substrates is a common process, especially in oligotrophic environments where access to essential elements is necessary for survival. Microbial dissolution of silicate minerals, such as feldspars and mafic minerals, contributes strongly to crustal weathering. Microbial colonies and biofilms attach to a mineral surface and obtain their nutrients by physical disaggregation of the minerals, as well as by dissolution through the production of organic acids (Konhauser et al., 1994; Konhauser, 2007). Etching patterns produced in the presence of actively metabolizing cells show clear differences to those produced by inorganic acids (Figure 4) (Welch et al., 2002). Microbial etching of volcanic glass (e.g., Thorseth et al., 1995) has recently received much attention because certain tunnel-like structures in ~3.5 Ga-old pillow lava rims from the Barberton and Pilbara greenstone belts have been interpreted as microbial corrosion biosignatures (Furnes et al., 2004; Banerjee et al., 2006).

Compositional variability can occur in minerals and rocks as a result of microbial metabolic activity. The distribution of elements (major, minor, and trace) in the

surfaces of minerals colonized by microorganisms may be different to that of the bulk mineral because the microorganisms leach out those elements that are important for their metabolic activities. For instance, sulfur can be leached from sulfides by sulfur-oxidizing bacteria (McGuire et al., 2001) and phosphorus from P-containing minerals is leached in P-poor environments (Taunton et al., 2000a, b). Also, unusual concentrations of trace elements may be associated with mineral-entombed microorganisms since the microbes preferentially concentrate elements that are necessary for their metabolic functions, such as Co, Ni, Cu, Mn, Mo, Se, and V, (Banfield et al., 2001).

The incorporation of organic compounds within a mineral structure may be indicative of biologically induced precipitation as, for instance, when microorganisms are permeated and entombed by minerals (Westall et al., 1995, 2000). Indeed, association of organic molecules with microfossils is a key complementary biosignature for traces of early life on Earth (Westall and Southam, 2006).

Whereas biologically controlled mineral growth produces specific crystalline shapes, biologically induced mineralization produces minerals with non-perfect habits (Banfield et al., 2001) due to alteration of the stability of the crystal surface in the presence of organics (Mann et al., 1993; Albeck et al., 1996). However, the presence of organic matter does not always have an influence on the morphology of a mineral precipitate. For instance, Orange et al. (2009) note that silica precipitated in nutrient media with and without cells had exactly the same structure, the only difference being the visible incorporation of EPS in the medium with cells.

A number of studies have noted a distinct difference in the size of minerals precipitated in the presence of microorganisms and those precipitated abiologically with the former being smaller than the latter. Douglas et al. (2008), for example, document smaller biofilm-induced calcite and Mn-oxyhydroxide mineral precipitates compared to abiogenic gypsum precipitates in an unusual microbial mat from a Death Valley pool.

Isotopic fractionation: Until recently, the preference of microorganisms for the lighter stable isotope of carbon ^{12}C over the heavier one, ^{13}C was considered to be one of the most important biosignatures in rocks. Indeed, Schidlowski (1988) had shown that these signatures can be traced back to rocks 3.8 Ga-old from the Isua province in Greenland. Recent studies, however, have demonstrated that $^{12}\text{C}/^{13}\text{C}$ ratios similar to those produced by living organisms occur in carbon produced by abiotic hydrothermal/metasomatic Fischer–Tropsch synthesis (e.g., van Zuilen et al., 2002). Contamination of the rock by younger organisms can also produce an erroneous biosignature. Westall and Folk (2003), for instance, identified Holocene fossilized endolithic microorganisms in the Isua banded iron formation that was used for Schidlowski's (1988) isotopic studies.

Biosignatures of structural components

Cells, colonies, biofilms, mats, EPS

Microorganisms generally occur as assemblages (colonies) of cells that may be monospecific, but, more often than not are plurispecies. Colonies are often linked by a film of polymers known as extracellular polymeric substances (EPS). Colonies coating a substrate in a two-dimensional manner are termed biofilms. Microbial mats are complex structures formed by layers of biofilms and may be microscopic to macroscopic in size, sometimes reaching dimensions of several square kilometers, for instance, on the floors of lagoons (e.g., Margulis et al., 1980). Although typically associated with the activity of photosynthetic microorganisms in shallow-water environments, microbial mats may also be constructed by non-photosynthetic microorganisms, such as the sulfur-oxidizers *Beggiatoa*, in deep-water habitats on the flanks of deep-sea hydrothermal vents and at hydrocarbon seeps (e.g., Kelley et al., 2005).

The structural components, cells, colonies, biofilms, mats, and EPS, may be preserved in rocks in a number of ways. Cells may leave organic walled impressions, mineral-coated or impregnated structures, or empty casts in a mineral precipitate. Biofilms and mats may also be preserved as organic impressions in sediments or mineralized structures.

Preservation of microbial structures

Organic walled structures: Cells walls can be preserved as organic impressions in fine-grained, anaerobic sediments (Javaux et al., 2001). The fixation of metals, such as Fe, on cell envelopes may retard lysis, thus contributing to the potential for preservation of cell walls (Ferris et al., 1988). While structures such as pollen spores are large enough to be visible in the rocks using light microscopy, individual microbial cells are often difficult to identify *in situ* in sediments because of their small size. Study of these organic remains is derived from palynological methods in which the detrital silicates encasing the cells are eliminated by acid-digestion of the rock. A major problem with this method is that microorganisms commonly colonize fractures in rocks, thus introducing younger contamination (e.g., Westall and Folk, 2003; Walsh and Westall, 2008). Such contamination led Pflug (1979) to identify eukaryotic yeast cells in a 3.8 Ga-old rock from Isua as *in situ* microfossils. This type of problem can be overcome by verifying the maturity of the kerogen by high-resolution TEM and Raman spectroscopy and/or by demonstrating chemical bonding between the organic molecules and the mineral matrix that indicates the syngenecity of the kerogen (Marshall et al., 2005; Derenne et al., 2008).

Mineralized microbial structures: The most common form of preservation of microbial structures is mineral fossilization. In this process, minerals bind to the organic surfaces of the cells/EPS in a passive reaction. The surfaces of microorganisms and EPS are very reactive, containing

ionized ligands to which mineral nuclei can attach themselves. The sorption reactions may take place via cation bridging, hydrogen bonding with functional groups such as carboxyls or hydroxyls, or by direct electrostatic fixation of the mineral to the functional groups (Lalonde et al., 2005). The attached nuclei then attract further nuclei, resulting in encrustation or permeation of the organic structure. The microbial surfaces and exopolymers therefore act as “mineralizing templates” (Konhauser, 2007). Depending upon the availability of the minerals in solution, the microorganisms may be completely entombed in a mineral precipitate. The type of mineral precipitated depends on the composition of the fluids and the redox conditions in the immediate environment of the microorganism. Many mineral phases can bind to microbial cell walls (Konhauser, 2007), including silica (Figure 1), carbonates (Ca, MgCa, Fe, Mn), metal oxides/hydroxides (Fe/Mn and magnetite), sulfates (Ca, Sr, Ba, Fe), sulfides (Fe, Ni, Pb, Zn, CuFe), phosphates (Ca), clays, and zeolites.

As noted above, cell wall composition and structure plays an important role in the fixation of metals because of the differential distribution of functional groups in different cell components. Mineral nucleation is similarly affected. Thus, Gram positive bacteria with their thick outer layer of peptidoglycan and the abundance of functional groups can be encased by a thick mineral crust, whereas the Gram negative bacteria with their thin layer of peptidoglycan sandwiched between an outer lipopolysaccharide layer and an inner phospholipid layer only fixed a thin, delicate crust (Westall, 1997). The latter author concluded that Gram negative cells therefore had less chance of being preserved in the rock record than Gram positive ones.

The cell walls of Archaea differ in their composition and structure to those of Bacteria and are also more variable. *Crenarchaeota* are characterized by a layer of paracrystalline proteins, the S-layer, which is loosely associated with the plasma membrane (NB: S-layers are also common around many species of Bacteria). The *Euryarchaeota* exhibit great variability in the composition of their cell walls, including a peptidoglycan-like component, pseudomurein. Experimental silicification of an Archaea having an S-layer, the hyperthermophile *Pyrococcus abyssi* showed that it produced a delicate silica crust, similar to that forming around Gram negative bacteria (Orange et al., 2009).

What is the fate of the organic components in a mineralized cell? Experimental fossilization shows that the macromolecules of the cell envelope may remain trapped in the mineral crust (Westall et al., 1995). The cytoplasmic space, on the other hand, may be empty after lysis, or, if lysis did not occur, it may contain balls of degraded macromolecules that can also nucleate minerals (in the process producing false nuclei, Westall et al., 1995). As noted above, the organic components of fossilized microbial structures may be preserved in anaerobic environments but they can be completely oxidized in

oxidizing environments. For example, the silicified remains of cyanobacteria in hot spring deposits from Yellowstone no longer contain any organic molecules (Cady and Farmer, 1996).

In order to be preserved in the rock record, the mineral-coated/permeated microbial structure needs to become encased in a mineral cement or by fine-grained sediments. Here, further diagenetic changes may take place, including changes in mineralogy (e.g., transformation of oxyhydroxides to oxides), replacement (complete or partial) of one mineral by another (e.g., silicification of carbonate mineralized remains), or dissolution. The final mineral or sediment-encased microbial fossils may exhibit different morphological preservation modes.

Artifacts: Abiological mineral precipitates can be notoriously confused with fossilized microorganisms. Many minerals may form simple spherical, oval, elongated, and even twisted morphologies. Silica spheres may occur in aggregates that look surprisingly like dividing microorganisms (e.g., Monty et al., 1991). Jones (2004) found that spherical silica aggregates nucleated onto a mucus thread in a siliceous hot spring forming filamentous structures that could possibly be mistaken for silica encrusted filaments. García-Ruiz et al. (2003) even showed that artificial mixed silica/organic precipitates could produce microbial-like morphologies (bacteriomorphs). However, these precipitates were not produced from naturally occurring solutions.

Examples of mineralized microbial structures: Microbial fossils occur throughout almost the whole of the rock record. The oldest known microfossils are found in silicified shallow-water volcanic sediments from the 3.5–3.3 Ga Barberton and Pilbara greenstone belts in which filaments, coccoidal and rod-shaped silicified microorganisms and associated EPS have been documented (Figure 1b) (Walsh, 1992; Westall et al., 2001, 2006a, b). [Older sediments from the 3.8 Ga-old Isua greenstone belt in Greenland are too highly metamorphosed to contain identifiable, syngenetic microfossils.] The very small size of the early Archaean microbial structures means that sophisticated instrumentation having high spatial and analytical resolution is necessary to observe and analyze them (Westall and Southam, 2006). Moreover, given the problem of establishing the biogenicity and syngenicity of microbial remains in these ancient sediments, multiple lines of evidence are required, including morphological, chemical, and isotopic biosignatures. In this way, Westall et al. (2006a, b) documented multispecies colonies of probable chemolithotrophic microorganisms within 3.446 Ga-old mudflat sediments from the Pilbara and microbial mats on the surfaces of littoral sediments in a 3.334 Ga-old formation from Barberton. The small crystal lattice of silica results in excellent preservation of fine textural detail, such as cell surface wrinkles (Westall et al., 2006a). Silicified (permineralized) microfossils occur throughout geological time (Knoll, 1985). Proterozoic formations contain extremely well-preserved cyanobacterial

fossils, for instance (Green et al., 1989), and silicified microfossils have been documented from numerous Phanerozoic hot spring environments (Jones et al., 2001; Jones, 2004).

The oldest calcified microfossils are relatively poorly preserved benthic cyanobacteria from the 2.6 Ga Campbellrand Subgroup in South Africa (Kazmierczak and Altermann, 2002). Well-preserved calcified microfossils occur in younger Proterozoic formations, such as the Draken Formation, Svalbard (Knoll et al., 1993).

Microfossils preserved by other minerals, such as pyrite, occur through much of the geological record, the oldest such fossils occurring in the above-mentioned 3.2 Ga-old massive sulfide deposits from the Pilbara (Rasmussen, 2000) and younger fossils occurring in the Proterozoic, e.g., pyritized filaments in stromatolites from the Altyn Formation of Montana (White, 1974), or pyritized biofilms coating soft body parts (Canfeld and Raiswell, 1991). Phosphatized microfossils are known from the Phanerozoic, for example, phosphate coatings on cyanobacteria in Cambrian sediments from Australia (Southgate, 1986) or phosphatized microbial biofilms on the soft body parts of Eocene eucaryotes (Liebig et al., 1996).

Microbialites and microbial fabrics in rocks

The physical expressions of microorganisms and the products of their enzymatic and metabolic activities result in microbialite structures and textures that are characterized by a particular internal structure or texture. They include a wide range of macroscopic to microscopic phenomena, such as stromatolites, thrombolites, oncolites, biolaminites, and crusts (Figure 3). Macro- to micro-scale fabrics and textures related to the presence of microorganisms also include MISS (the MISS of Noffke et al., 2003), and microfossils (Burne and Moore, 1987; Monty et al., 1995; Riding and Awramik, 2000). Microbialites and microbial fabrics are found in rocks throughout the geological record with the oldest stromatolites occurring in 3.5–3.3 Ga-old formations in the Pilbara of Australia and in Barberton, South Africa (Lowe, 1980; Walter, 1983; Byerly et al., 1986; Hofmann et al., 1999; Allwood et al., 2006). The biogenic origin of the early Archaean stromatolites has been challenged by Lowe (1994) and Lindsay et al. (2005) but Riding (2008) suggests that some of the Precambrian stromatolites may be mixtures of microbial and abiogenic, stromatolite-like fabrics. The large and diverse stromatolites characteristic of the Proterozoic declined in importance throughout the latest Precambrian to Cambrian times and, from the early Cambrian onwards, microbialite structures are dominated by microbial mounds formed by non-stromatolitic calcifying microbes (e.g., cyanobacteria, Monty, 1995). Microbial mounds are well-developed throughout the geological record spanning from the Proterozoic to the Recent in both shallow- and deep-water settings and are considered to be a significant expression of the history of Earth's microbial life (Figure 2) (Monty, 1995). Both stromatolites and

microbial mounds are characterized by the activity of microbes which calcify, trap, and bind sediments, forming delicate and persistent microstructures rich in micrite (microcrystalline calcite) and organomicrite. Microbially generated mounds and microbialites formed in shallow-water environments mainly involve photosynthetic/phototrophic and heterotrophic microbes. In deeper waters, however, chemosynthetic microbes are associated with hydrocarbon seeps and hydrothermal-related mound deposits (Peckmann and Thiel, 2004). Deep-water stromatolitic fabrics and crusts have been described from hydrocarbon seeps on the Aleutian accretionary margin as a product of methane-consuming Archaea (Greinert et al., 2002).

The most common microbially induced fabrics from carbonate rocks are clotted and peloidal fabrics (Burne and Moore, 1987; Shapiro, 2000; Flugel, 2004). These fabrics consist of spherical-to-elliptical microscopic aggregates of microcrystalline clots or peloids (Figure 5a) (e.g., calcite, aragonite), cemented by carbonate and/or sediments (MacIntyre, 1985; Shapiro, 2000). Fenestral and stromatactis fabrics from organic-rich sedimentary deposits (Figure 5b), such as microbial mounds or geothermal springs (e.g., travertine), are microbiological in origin (Flugel, 2004). Encrustations, concretions, and coatings are generally microbial products that contain a record (morphological, geochemical, and/or isotopic) in their sedimentary phases of the biochemical processes involved in their genesis (Raiswell and Fisher, 2000; Kiriakoulakis et al., 2000). For instance, Fe-Mn coatings and pyritiferous carbonate nodules are considered to be microbial fabrics (Peckmann and Thiel, 2004).

Microbially induced sedimentary structures (MISS) are formed by the rhythmic alternation of photosynthetic microbial mats and sediments in mudflat environments (Noffke, 2008). MISS are widespread in the geological record and have also been identified in sediments 3.2 Ga-old from South Africa (Noffke et al., 2003).

Banded iron formations (BIFs) occur throughout the rock record from 3.8 Ga onwards (BIFs occur in the Isua greenstone belt in Greenland). The influence of microorganisms on the formation of these laminated accumulations of iron oxides and chert is the subject of much controversy. Photochemical oxidation of ferric iron of hydrothermal origin is one explanation (Cairns-Smith, 1978) but other biological controls have also been suggested, such as oxidation by oxygenic photosynthesizers (Cloud, 1965), or simple sorption of Fe^{2+} onto microbial cell surfaces to catalyze a basically abiological precipitation process (Konhauser, 2000), or the precipitation of Fe oxides by Fe oxidizing microorganisms (Posth et al., 2008).

Relevance of biosignatures and their astrobiological implications

We have seen above that a number of the biosignatures described can be imitated by abiological processes

Biosignatures in Rocks, Figure 5 Micrometer-scale biosignatures in rocks. Transmitted light photomicrographs of petrographic thin sections. (a) Continuous and planar laminations of stromatolite structures from the Devonian Hollard Mound (Morocco). The arrows indicate the spar-filled cavities generating fenestral fabrics. (b) Detail from (a) showing a lamina of fine gray micrite (m) that locally consists of microbially produced peloids (arrows). Scale bars: (a) = 5 mm; (b) = 200 μ m. (Images reprinted with permission from Cavalazzi, 2007, and Cavalazzi et al., 2007).

resulting in significant controversy. These are serious limitations when searching for the first traces of life on Earth or for biosignatures on other planets. How can nonliving molecules be distinguished from very primitive living cells – and in the fossilized form? A carbon isotope signature on its own is not sufficient because it could be either abiogenic or biogenic in origin. A collection of simple-shaped minerals, even joined together with compromised boundaries, could represent abiogenic precipitates or possibly a fossilized microbial colony. Identification of biosignatures in ancient terrestrial or extraterrestrial materials therefore needs to be based on a combination of structural, chemical, and isotopic traces that are related to the three main characteristics of living organisms: their physical structures, the chemical components of the structures, and their metabolic or living processes (Westall and Southam, 2006; Westall, 2008). Another aspect to take

into account is the fact that living organisms by their very existence and metabolism interact with and influence their immediate environment.

On a biotic world where the context of structure, fabric, and composition are well-constrained, certain characteristics, such as element enrichment, mineral composition, shape, and size can be used as complementary evidence for the existence of living organisms. Can these characteristics be used on a world where the existence of life forms is uncertain, for instance on the primitive Earth or Mars? Prebiotic molecules of mostly extraterrestrial origin, characterized by a wide range in composition and structure, including simple amino acids, polycyclic acidic hydrocarbons (PAHs), thiophenes, fullerenes etc. (Cronin, 1998), abounded on these worlds (Maurette et al., 2000). Could prebiotic organic macromolecules scavenge elements from the environment in the same way as biomolecules and, if so, would some elements be preferentially fixed? These macromolecules have very few of the functional groups that characterize biogenic molecules, and it is therefore unlikely that they will be able to induce significant metal fixation. Thus, element concentration and distribution in potentially biogenic materials (organic or mineralized organics) could be considered as a useful complementary biosignature when associated with other types of biosignatures. Could prebiotic organic molecules induce mineral precipitation? Again this is unlikely since biominerals precipitate because of changes in the environment caused by the excretion of metabolic waste products, or enzymatic mediated changes in the redox state, or the presence of a charged cell surface that attracts mineral nucleation, conditions that are not met by prebiotic molecules. On the other hand, the physical presence of prebiotic molecular matter in an environment where minerals are being precipitated abiotically from supersaturated solutions (saline ponds, hot springs, the early, silica-saturated oceans) could eventually have an influence on the size and shape of minerals because of alteration in the stability of the crystal surfaces (cf. Mann et al., 1993; Albeck et al., 1996).

Once the biogenicity and syngenicity of the different biosignatures in a rock have been established, how are they to be interpreted? What do they tell us about the community of microorganisms that lived in a particular environment? Are all the original microorganisms in the community preserved? This is particularly relevant because not all microorganisms can be fossilized. For instance, Orange et al. (2009) noted that, although two species of thermophilic Archaea, *Pyrococcus abyssi* and *Methanocaldococcus janaschii* had similar cell wall structures and compositions, the former could be experimentally silicified whereas the latter naturally lysed before mineral nuclei could fix to the cell walls.

Another aspect of the study of biosignatures is the importance of observation and analysis at the scale of the microorganisms (Westall and Southam, 2006; Westall, 2008, 2009). Many fossilized microorganisms are very small and cannot readily be distinguished from abiogenic

mineral accumulations at the optical microscope scale. They need to be studied using higher-resolution electronic microscopes. The question of scale is also pertinent to analysis of chemical or isotopic signatures. What information about the microbial community is provided by isotope measurements made on kerogen extracted from the bulk rock when the rock may contain traces of different microbial communities at the micrometer scale? The microbial communities (colonies, biofilms, and mats) may, themselves, consist of multiple species, thus, resulting in additional mixture of the isotopic signature. To complicate matters even further, specific components of an individual cell may have different isotopic signatures. For example, van de Meer et al. (2000) note that the carbon isotope composition of the lipids of *Chloroflexus aurantiacus* differ from the bulk isotopic composition of the cells. This means that isotope measurements made even *in situ* (e.g., with a spot size of ~50 μm , van Zuilen et al., 2007) need to be interpreted with caution.

Conclusion

While it is clear that the study of biosignatures in rocks is not without difficulties, these can be overcome by combining signatures of the different aspects of living organisms, i.e., structural, chemical, and isotopic traces, as well as evidence for the interaction of living organisms with the environment. Further investigation of the microbial communities that produced the biosignatures needs to be undertaken at the microbial scale in order to obtain relevant information about the types of organisms and their metabolic activities. This is a challenge for spatial and analytical resolution but it is this level of detail that is necessary for disentangling the bulk biosignatures from those produced by the individual microorganisms and for better understanding the complexity of past communities.

BIOSILICIFICATION

The biological formation of opal-like amorphous hydrated silica. This phenomenon occurs on a globally vast scale in a wide variety of organisms, including protists, radiolarian, foraminifera, sponges, molluscs, brachiopods, copepods, ascidians, diatoms, and higher plants. See entries “*Silica Biomineralization, Sponges*”, “*Microbial Silicification – Bacteria (or Passive)*” and “*Microbial Biomineralization*” for further reading.

BLACK SHALES

Wolfgang Oschmann
 University of Frankfurt, Frankfurt, Germany

Definition

Most modern and ancient aquatic (marine, brackish, and lacustrine) environments were sufficiently oxygenated to permit colonization by numerous benthic, planktic, and nectic organisms. Due to excess oxygen the biologically produced organic matter is rapidly degraded. The sediments formed thereby exhibit only very low amounts of organic matter.

In contrast, very high rates of primary production and/or stagnant water bodies result in black shale sedimentation, which is associated with oxygen depletion or even lack of oxygen within the substrate and to some extent also within the water column. Degradation of organic matter is incomplete, partly by anaerobic bacteria, causing strong enrichment of organic matter in sediments. Black shales therefore commonly exhibit excellent preservation of organic molecules and mineralized soft tissues and hard parts of organisms.

The importance of black shales for scientists and the society are twofold. Black shales serve as source rocks for fossil fuels (oil and gas), which cover most of the energy needs of modern societies, and due to excellent preservation they provide particular sites for palaeontological studies.

Sedimentary characteristics of black shales

Black shales sediments in common are dark gray to black in color and are characterized by microlaminations, which may vary from distinct to blurred. The lamination is caused by quiet depositional conditions and the scarcity or lack of bioturbation. In many cases, the lamina were formed by alignments of fecal pellets ([Figure 1a](#)), which rained down in great numbers from surface waters. The

Black Shales, Figure 1 (a) Indistinct type of lamination formed by alignments of fecal pellets within bituminous mudstone facies (Kimmeridge Clay, Yorkshire, England, thin-section). (b) Most pellets are rich in carbonate and consist of coccoliths and coccospheres (Kimmeridge Clay, Yorkshire, England, SEM-view). (c) Organic rich filamentous mat-structures of bacterial origin (orange color) with dispersed silt-sized sedimentary particles (white) and pyritic aggregates (black) (thin-section, Kimmeridge Clay, Yorkshire). (d) SEM-view of a framboidal pyrite consisting of pyritohedral microcrystals precipitated during iron and sulfate reduction (Kimmeridge Clay, Yorkshire).

diameters of fecal pellets exceed the average annual sedimentation rate by far, and cause indistinct to blurred types of lamination. Commonly, it is assumed that seasonal variation in sedimentation (clastic input vs. primary production) may cause microlamination. However, the low sedimentation rates in general practically hamper a clear proof of varves.

Black shales typically consist of four main components (e.g., Röhl et al., 2001). *Siliciclasts*, mainly clay to silt sized particles form the major component of the rocks (50 to >90 wt.%). They derive from fluvial or aeolian input from hinterland areas. *Carbonates* originate either as skeletal remains of phytoplankton organisms (e.g., coccoliths, Figure 1b), or they are precipitated during early diagenesis at or close to the sediment surface (Frimmel et al., 2004). Their content varies remarkably. The proportion of *organic matter* may vary between 0.5 and 50 wt.% of the whole rock. It mainly derived from surface water primary production, but detritus from land plants and bacterial organic matter may also contribute. Black shales with a content of organic matter below 10% are termed as bituminous mudstones, and above 10% as oil shales. *Pyrite* (FeS_2) in black shales occurs as finely dispersed tiny framboids (Figure 1d), which were formed as syngenetic precipitates due to bacterially driven iron- and sulfate-reduction. In case of excess organic matter, larger pyrite aggregates may be formed during

diagenesis. The proportion of pyrite reaches 10–20 wt.% maximum.

History of organic matter preservation

During the early history of the Earth and life (Hadean and Archaean periods), virtually no free oxygen existed in the ocean and atmosphere. After oxygenic photosynthesis was established and the formerly reduced compounds had been oxidized, free oxygen started to accumulate in the ocean and the atmosphere ca. 2.2 billion years ago (e.g., Catling and Claire, 2005; Rouxel et al., 2005). The first eukaryotic organisms with highly resistant organic cell walls (acritarchs and/or primitive green algae) evolved during late early Proterozoic times (e.g., Samuelsson et al., 1999; Arouri et al., 2000). Their remains escaped rapid degradation and formed a major sink for organic carbon. Large quantities of organic matter had been embedded within marine sediments, leading to the first black shale formation (e.g., Banerjee et al., 2006). At least since Phanerozoic times, the atmosphere showed roughly the present-day oxygen levels (Catling and Claire, 2005; Berner, 2006) and aerated conditions persisted in the oceans. However, certain climatic and geographic factors promoted sluggish circulations with reduced turn over rates, thus preventing mixing of the water column. Related environments are commonly

controlled by a temporary or permanent density-stratification (thermo- and/or halocline) within the water column (e.g., Demaison and Moore, 1980; Oschmann, 1988; Wignall, 1994).

Oceanographic models for oxygen depletion and black shale formation

Certain combinations of physical and biotic factors cause oxygen depletion within marine areas, and have been described in various models from modern and ancient environments. In the following, a brief overview on the various models and fossil examples are given. Fossil examples in many cases however, were described in more than one of these models.

Silled basins

Land - locked silled basins with a positive water balance and a shallow and narrow connection to the open sea are characterized by a low salinity surface water outflow and a high salinity deeper water inflow (estuarine circulation). The difference in density between low and high salinity waters results in a permanent halocline and subsequently, thermocline. As convection and influx of oxygen to lower parts of the water column are prohibited, anoxic conditions develop below the halocline. The Baltic Sea and the Black Sea (e.g., Bahr et al., 2005, 2006) represent modern examples. Proposed fossil examples are e.g., the Permian Kupferschiefer (e.g., Bechtel and Püttmann, 1997) and Toarcian black shales in Central Europe (e.g., Röhl et al., 2001; van de Schootbrugge et al., 2005).

Upwelling systems

Today, upwelling is known from western continental margins in subtropical areas. Trade winds cause an offshore flow of surface waters and force oxygen-poor and nutrient-rich bottom waters to ascend. The mixing with oxygen-rich surface waters results in a very high plankton productivity and export production to the sea floor. Decomposition consumes all available oxygen, resulting in stagnant conditions and enrichment of organic matter in and on the sediment. Well-known modern to Pleistocene examples are the coastal areas off Peru and off Namibia (e.g., Wefer et al., 1996; Berger and Wefer, 2002; Hebbeln et al., 2002).

Oceanic anoxic events (OAEs)

Oceanic anoxic events (OAEs) were characterized by oxygen depletion in intermediate waters in major parts or even complete ocean basins. They were explained by a number of factors, namely (1) intensified deep water formation in high latitudes, (2) origin of warm and saline bottom waters at low latitudes, (3) enhanced fresh water runoff from continents associated with high rates of nutrient delivery, and (4) increased primary production associated with extreme greenhouse conditions. These factors all favor the development of low oxic to anoxic conditions with increased organic matter preservation. A modern to

Pleistocene example is the Arabian Sea in the low-latitude Indian Ocean (e.g., Schmiedl and Mackensen, 2006). Numerous OAEs occurred during the Earth's history, of which the Cretaceous OAEs are the most widely known. They are explained by high organic carbon burial related to global warming and greenhouse periods (e.g., Erbacher et al., 2001; Herrle et al., 2003). Many of these events were probably regional occurrences within restricted basins. However, there is increasing evidence for an open ocean and maybe global extension of the OAE 2 at the Cenomanian/Turonian boundary (e.g., Erbacher et al., 2005).

Eutrophic shelf

Many modern shelf environments (e.g., North Sea and Adriatic Sea) are characterized by man-made eutrophication that stimulates primary production with subsequent oxygen consumption and accumulation of organic matter (Dethlefsen and von Westernhagen, 1983; Kollmann and Stachowitsch, 2000). Fossil examples refer to a number of epicontinental seas particularly during the periods of greenhouse climate (e.g., Kimmeridge clay in western Europe (Oschmann, 1990; Miller, 1991), Toarcian black shales (van de Schootbrugge et al., 2005)).

Tidal mud flats and shallow lagunal environments

Most of the land-derived organic matter is deposited in near-shore environments, particularly in tidal mud flats. Additionally, land-derived nutrients stimulate primary production and subsequent oxygen depletion, thus promoting the enrichment of organic matter in the sediment (e.g., Wilms et al., 2006; Rink et al., 2007). Well-known fossil examples refer to the middle and late Triassic tidal and shallow subtidal mud flat areas from the northern Tethyan margin, e.g., at Mt. St. Giorgio, Switzerland (Röhl et al., 2002) and Seefeld, Austria (Hopf et al., 2001).

Black shales as ecosystems

Black shales and modern oxygen-depleted environments show various geochemical and ecological characteristics indicative of increasingly harsh life conditions (Table 1). Rhoads and Morse (1971) distinguished aerobic, dysaerobic, and anaerobic biofacies within marine environments. This classification has subsequently been used in many studies of modern and ancient oxygen-controlled environments (e.g., Tyson and Pearson, 1991; Wignall, 1994). Observations from modern environments show a remarkable seasonal oxygen fluctuation (Oschmann, 1994, 2000). Therefore, a modified scheme of classification was introduced, where the term dysaerobic was replaced by poikiloaerobic to address seasonal variation in oxygen supply.

The proportions of organic matter, pyrite, and biomarkers increase from the aerobic toward the anaerobic biofacies. In the same direction, the diversity of eukaryotes diminishes. Particularly, deep burrowing organisms

Black Shales, Table 1 A synoptic sketch of the geochemical and ecological characteristics of modern and fossil aerobic, dysaerobic/poikiloaerobic, and anaerobic biofacies

Biofacies			Aerobic	Dysaerobic/poikiloaerobic			Anaerobic

Position of redox boundary:		Deep in substrate	Close to sediment surface			Within the water column		

are affected by the rise of the redox boundary and try to settle close to the sediment surface (Oschmann, 1994; Schmiedl and Mackensen, 2006). Additionally, the proportion of organisms with benthic (lecithotrophic) larval development decreases with increasing oxygen depletion. If the redox boundary finally migrates out of the substrate, eukaryotic life is excluded. Dwarfs with body size remarkably smaller than normal and juveniles occur within the dysaerobic/poikiloaerobic facies, whereas microbial mats and partly also larval shells can be found within the anaerobic facies. The sporadic occurrence of the latter indicates failed larval spatfalls during unfavorable conditions.

Conclusions

1. Black shale sediments mainly form in marine to brackish waters under low oxic to anoxic conditions.
2. They are characterized by remarkably enriched proportions of organic matter and pyrite. The organic matter derives from marine primary production, terrestrial input, and bacterial derived compounds.
3. Black shales date back to late Proterozoic times and are widespread during Phanerozoic age.
4. Origination of black shales is explained by a number of models. A common aspect of most of these models is the formation of a density stratified water column, which prevents oxygenation of deeper waters.

5. The degree of oxygen depletion in benthic ecosystems during black shale deposition can be reconstructed by a number of geochemical and ecological features.

Break-up of the supercontinent Rodinia

Definition

Supercontinent Rodinia. The earth's geodynamic system periodically pushes almost all continents together to form a single landmass – a supercontinent. The best known supercontinent is Pangaea (or Pangea) that existed between 320 and 170 Ma. A less known supercontinent Rodinia is believed to have existed between 900 Ma (some believe 1,000 Ma) and 750 Ma. The name “Rodinia” was coined by McMenamin and McMenamin (1990) from the Russian word “rodit” meaning “to beget” or “to give birth.” McMenamin and McMenamin (1990, p. 95) considered Rodinia to have been the supercontinent that spawned all subsequent continents, while “the edges (continental shelves) of Rodinia were the cradle of the earliest animals.” Three landmark paper in 1991 (Moores, 1991; Dalziel, 1991; Hoffman, 1991) triggered a global debate on this supercontinent hypothesis. The configuration of Rodinia is still controversial today, with some alternative reconstructions given in Hoffman (1991), Pisarevsky et al. (2003), and Li et al. (2008) (Figure 1).

The breakup of Rodinia: introduction

Although it is widely accepted that Rodinia broke apart during the latter half of the Neoproterozoic era (1,000–542 Ma) and that some fragments reassembled by the early Cambrian (*ca.* 530 Ma) to form Gondwanaland (Hoffman, 1991), our knowledge of the timing of the breakup events and the processes involved is still sketchy.

Record of Rodinia breakup

The breakup of Rodinia was recorded both geologically and geophysically. The most important geological records of the breakup process are globally widespread continental rift deposits and related magmatism, and records of the geological transition from continental rifting to passive margin deposits where rifting succeeded to form new oceans. One of the best matches of rifting records between continents is that between southeast Australia and South China, where episodes of rift-related magmatism at *ca.* 825 Ma, 800 Ma, 780 Ma, and 750 Ma have been well documented (Preiss, 2000; Li et al., 2003) (Figure 2). Similar records are emerging from other continents.

Radiating dyke swarms and remnants of large igneous provinces (LIPs) have also been regarded as important geological records of the breakup of Rodinia (Figure 2c and d; see discussion below under *Mechanism for the breakup*).

The most important geophysical constraint on the breakup of Rodinia is provided by paleomagnetism. Whereas, an individual pole of a given age for a continent constrains its paleolatitude at that time but not its paleolongitude, comparable apparent polar wander paths (APWPs) for different continents can indicate a unique paleogeographic fit between them. In the latter case, when two matched APWPs start to diverge, it implies that the two continents started to move independently (*i.e.*, a breakup between them occurred). Unfortunately, such an ideal situation has rarely been identified for the Rodinia time because of the limited data currently available.

Timing of events

The ages of continental rifting events can be easily dated because of the availability of datable minerals such as zircon in the rift-related magmatic rocks, and it is now widely accepted that continental rifting in the lead-up to Rodinia breakup started at *ca.* 825 Ma or earlier (see summary in Li et al., 2008; Figure 2). However, the timing of the breakup events is still controversial, and different parts of the supercontinent seem to have broken apart at different times.

The stratigraphic record in southeast Australia indicates a rift-drift transition between the Sturtian glacial deposits (with a poor age constraint of *ca.* 750–690 Ma) and the overlying sag-phase deposits (Powell et al., 1994) that were recently dated at between 657 ± 5 and 643 ± 2 Ma (Re-Os ages, see Kendall et al., 2006). These age

Breakup of Rodinia, Figure 1 Three of the alternative Rodinia reconstructions: (a) Hoffman (1991), (b) Pisarevsky et al. (2003), and (c) model adapted by IGCP440 for the Geodynamic Map of Rodinia. (Li et al., 2008.)

constraints seem to agree with those for south China and western Laurentia. Although rifting occurred at *ca.* 750 Ma along the eastern margins of Laurentia, the breakup there appears to have occurred during *ca.* 615–570 Ma (Cawood and Pisarevsky, 2006). These younger events are possibly recognizable in global tectonic subsidence curves (Bond et al., 1984).

Such geological evidence for the breakup of Rodinia is sometimes at variance with paleomagnetic constraints. Paleomagnetic data suggests that India was either adjacent to western Australia (Torsvik et al., 2001) or had already broken away from Rodinia at 750 Ma (Figure 3b). South

China must also have broken away from Australia and Laurentia by 750 Ma if it occupied a central position in Rodinia as shown in Figures 1c and 3a (Wingate and Giddings, 2000; Li et al., 2008). Alternatively, Rodinia may have remained intact at *ca.* 750 Ma if a different configuration occurred (see Fig. 5 of Li et al., 2004).

Mechanism for the breakup

The most commonly invoked mechanism for the breakup of Rodinia is the activity of mantle plumes or of a mantle superplume (superswell) beneath the supercontinent,

Breakup of Rodinia, Figure 3 Cartoons illustrating the breakup process of Rodinia. (After Li et al., 2008.)

which thinned and thermally weakened the lithosphere resulting in widespread continental rifting and eventually breakup (Figure 3a and b).

Evidence for plume/superplume activity during the time of Rodinia include remnants of LIP and radiating dyke swarms (Figure 2c), syn-magmatic, continental-scale doming indicating the arrival of a plume-head (Li et al., 1999), large-scale anorogenic but often dominantly felsic melting that requires a pan-Rodinia introcontinental heat source (Li et al., 2003), and abnormally high-temperature ($>1,500^{\circ}\text{C}$) mantle melting (Wang et al., 2007). Mechanisms proposed for the formation of such a superplume (or superswell) include thermal shielding by the supercontinent (e.g., Anderson, 1994), gravitational push-up effects on the hotter lower mantle by circum-Rodinia avalanching slabs (Li et al., 2004, 2008), return flow of whole-mantle convection (Zhong et al., 2007), and partial melt of recycled mid-ocean ridge basalts near the core-mantle boundary under Rodinia (Maruyama et al., 2007).

Summary

The breakup of Rodinia was a diachronous and protracted process. Widespread continental rifting started at *ca.* 825 Ma when Rodinia spanned from the equator to high latitudes (Figure 3a), but the breakup, initially between Australia/East Antarctica, Laurentia, and possibly South China did not occur until *ca.* 750 Ma (Figure 3b) or later when the supercontinent was centered on the equator. Gondwanaland was already assembling before some of the West Gondwanan continents broke away from Laurentia at *ca.* 600 Ma (Figure 3c), and by the early Cambrian (530 Ma) the assembly was complete (Figure 3d). The breakup of Rodinia is believed by some to have been related to the formation of a mantle superplume beneath the supercontinent.

BIOFILMS AND FOSSILIZATION

Joachim Reitner

University of Göttingen, Göttingen, Germany

Synonyms

Carbonaceous bacterial biofilms; Hautschatten

Definition

Microbial biofilms cover normally in aquatic environments dead organisms and control partly the process of decay. The soft tissues of the body outline are preserved as a layered structure which comprises a carbonaceous microbial biofilm, in the literature often called “Hautschatten” (Figure 1). Fossils with soft part preservation are extremely rare, but under certain circumstances, like suboxic or anaerobic conditions, remains of their soft tissues with detailed histological fabrics are found. The evidence of non-biomineralized soft tissue normally degrading completely during decay is linked with special microbial processes. This exceptional preservation requires soft tissues to be replicated by authigenic minerals or pseudomorphed by bacterial biofilms (e.g., Wuttke, 1983; Toporski et al., 2002; Briggs, 2003). The different organs in many cases often exhibit different microbially controlled lithified biofilms with an unusual preservation of involved microbes.

Geobiological implications and examples

Understanding the relationship between decay and mineralization is of fundamental importance to palaeontologists

interested in the record of soft-bodied organisms. Soft-bodied fossils also provide insights into early diagenetic processes in sediments and give basic information on related organic geochemistry. The lack of biomineralized hard parts in many organisms is the normal condition in the fossil record. However, the mode of soft-tissue decay is far from uniform and the sum of various processes results in a preservation in so-called Konservat-Lagerstätten (Seilacher, 1970; Seilacher et al., 1985).

Derek Briggs and his group have made fundamental experiments on how the preservation of soft-tissues works (e.g., Briggs, 1999, 2003; Briggs and Kear, 1993; Briggs and Wilby, 1996; Grimes et al., 2001; Gupta et al., 2006). For example, they could demonstrate that initial pyritization of a plant tissue can be an extremely rapid process (within 80 days) and is driven by anaerobic bacterially mediated decay. They have made comparable experiments mainly with arthropods. Toporski's and coworkers' (Toporski et al., 2002) investigation on the Oligocene Enspel Maar black shale is a milestone in the research on soft-tissue preservation via microbial biofilms. The multitask biogeochemical analyses give the deepest insight into the taphonomy of soft tissue and microbial-related decay processes. The most famous locality with preserved soft tissues is the Eocene Messel locality. From this locality, soft tissues covered with lithified biofilms were first described by Wuttke (1983). Thick microbial biofilms are generally much darker than the surrounding black-shale and form the so-called “Hautschatten” and were for a long time believed to represent fossilized soft tissues. The biofilms trace back the decaying soft tissue in an anaerobic environment and “casting” of the former soft tissues. Often the digestive

Biofilms and Fossilization, Figure 1 A very well-preserved mouse (*Apodemus atavus*) from the late Pliocene fossil lagerstaette Willershausen (Lower Saxony, Germany) with perfectly preserved biofilm-related “Hautschatten” with visible remains of the former fur (Geoscience Museum University of Göttingen).

system of large fossils is excellently preserved (Franzen, 1994). Fundamental studies on biofilm soft-tissue relationship were carried out by Richter (1994) and Liebig (1997). Another intriguing example is the “soft-tissue” preservation in dinosaur bones (Kaye et al., 2008). Kaye and coworkers have found microbially altered soft tissue in a dinosaur bone and they give a critical explanation of this fact. Within their paper they discuss the processes of tissue preservation and also demonstrate the importance of recent microbial biofilm invasion and late diagenetic alteration of primarily formed pyrite framboids. The clou of this investigation is also that there is no real soft-tissue preservation – however, preserved biofilms cast the former tissue and give an idea about the original structures.

All “Hautschatten” soft-tissue preservations are probably preserved lithified biofilms and not real soft tissues.

Conclusion

Biofilms play a significant role in suboxic and anaerobic milieus preserving soft tissue remains. The body outline of dead organisms is exactly traced by the margins of the mineralised biofilms and give a perfect image of the entire fossil. These structures are often called after the German word “Hautschatten”-preservation and is commonly found under black shale condition.

BIOFILMS

Joachim Reitner

University of Göttingen, Göttingen, Germany

Definition

Nearly all hard surfaces exhibit biofilms, organic coatings of microbial cells which are enclosed in extracellular polymeric substances (EPS). Biofilms interact between hard substrates such as minerals and rocks, water bodies, and the atmosphere. Metabolic exchange processes controlled by biofilms, globally influence bio-geochemical cycles.

Biofilms and microbial mats are benthic systems formed by different microbial communities which secrete hydrated mucus substances (EPS) (e.g., Characklis and Wilderer, 1989; Costerton et al., 1987, 1995) in various amounts. These EPS substances are mainly polysaccharides, glycoproteins, exoenzymes, and nucleic acids (Sutherland, 1977; Decho, 1990; Wingender et al., 1999). Biofilms and microbial mats display a continuous spectrum ranging from thin micrometer-sized coatings of mono-specific and poly-specific microbial populations up to centimeter thick communities of various microbes such as archaea, bacteria, eukaryotic algae, fungi, and protozoa. In many cases, these thick microbial mats exhibit a clearly visible ecological zoning owing to the presence of different microbial communities which are often characterized by colored pigments. The geobiological importance of microbial mats was recognized early by geoscientists (Walcott, 1914; Black, 1933; Pia, 1933) in contrast to the hardly visible biofilms which are globally much more widespread. Engineers and microbiologists, for example, Characklis and Wilderer (1989); Flemming (1991); Muyzer et al. (1993); Costerton et al. (1987), (1995); Neu and Lawrence (1999), have recognized the enormous importance and potential of biofilms in

Biofilms, Figure 1 Cyanobacterial biofilm forming a modern aragonitic stromatolite (Walker Lake, Nevada). Biofilm is dominated by filamentous cyanobacteria – *Calothrix* (C). Few coccoid cyanobacteria are also present (CC). Within the youngest lithified part, remains of cyanobacterial sheets are visible (LS).

many common processes. Geoscientists have increasingly investigated the rock- and mineral-forming potentials of biofilms in the 90s of the last century (e.g., Ferris, 1991; Pedley, 1992; Reitner, 1993). Biofilms were also found in deep subsurface environments and, significantly for the Deep Biosphere, up to the upper known temperature limit of life (110–120°C) (Pedersen, 1993; Fyfe, 1996; Gold, 1999; Stetter, 1994, 1996).

Organo-films are special organic coatings which are formed by various macromolecules and do not contain living cells. Organo-films are taphonomic remains of biofilms or newly formed from biogenic degradation products (geopolymers sensu Killops and Killops, 1997; Gold, 1999). Adsorption on mineral surfaces and self organizing catalytic processes play a central role during formation (Ferris et al., 1996; Reitner, 1993).

Stromatolites, thrombolites, and generally microbialites, are lithified products of bio- and organofilms, as well as thick microbial mats (Figure 1).

SILICA BIOMINERALIZATION, SPONGES

Hermann Ehrlich
 Dresden University of Technology, Dresden, Germany

Synonyms

Biosilicification, Silication

Definition

Biosilicification: The biological formation of opal-like amorphous hydrated silica. This phenomenon occurs on a globally vast scale in a wide variety of organisms, including protists, radiolarian, foraminifera, sponges,

molluscs, brachiopods, copepods, ascidians, diatoms, and higher plants.

Biom mineralization and biosilicification

Introduction

The growth in geobiology and biogeochemistry has led to a number of new existing research areas where the distinctions between the biological, chemical, and earth science disciplines melt away (Weiner and Dove, 2003). Of the intriguing topics that are receiving renewed attention, the study of biomineral formation based on organic templates is one of the most fascinating topics today. During the processes of biomineralization, the organic material acts variously as nucleator, cooperative modifier, and matrix or mold for the mineral ions with respect to biominerals formation which are characterized by a hierarchical order (Bäuerlein, 2007).

Biominerals may be deposited within the organism, and within its immediate surroundings or environment, as a result of the metabolism of the living creature (Skinner, 2005). The physiological pathways by which organisms precipitate skeletal minerals and the forms and functions of the skeletons they fashion have been shaped by natural selection through geologic time, and all have constrained continuing evolution in skeleton forming clades (Knoll, 2003). The variety of biomineralizers recently reviewed by Ehrlich et al. (2008a) can best be expressed by the fact that, approximately 128,000 species of molluscs, about 800 species of corals, 15,000 species of sponges including 550 species of glass sponges, 700 species of calcareous green, red and brown algae, more than 300 species of deep-sea benthic foraminifera, and 200,000 diatom species (Mann and Droop, 1996) exist.

Precipitation of silica on organic templates could have been abiotic, in which organic matter merely serves as a template for nucleation, or biogenic, i.e., induced by biological activities or a combination of both (Mukhopadhyay et al., 2004). Silicon, in the form of silicic acid, is a fundamental nutrient for diatoms, silicoflagellates, radiolaria, and many sponges, all of which polymerize it to build skeletons of biogenic silica (Maldonado et al., 2005).

Sponges

Sponges (Porifera) are the most simple and ancient multicellular animals on earth and live attached to the seabed or another substratum. Sponges diverged from other animals earlier in evolutionary history than any other known animal group, extant or extinct (Reitner and Mehl, 1996), with the first sponge-related record in earth history found in 1.8 billion year old sediments (Nichols and Wörheide, 2005). The huge diversity with respect to their natural habitat is probably the reason for the estimated number of approximately 15,000 different sponge species (Hooper and van Soest, 2002). To support life, sponges pump huge amounts of seawater (170–72,000 × their own body volume per day) through their bodies (Simpson,

1984) and filtrate it to capture food particles, such as bacteria, micro algae, other unicellular organisms, or dead organic particles. The whole sponge body is designed for efficient filtration of the surrounding seawater, which is essential because of the low nutrient availability at the sea floor.

The phylum Porifera (sponges) is divided into three classes, Hexactinellida and Demospongiae that comprise a siliceous skeleton and the Calcarea with a calcareous skeletal network (Bergquist, 1978). Significant separation of the Calcarea from the Hexactinellida/Demospongiae (Silicispongia) clade is also implied by fundamental differences in morphology and development: unlike Silicispongia, calcareans lack morphologically distinct microscleres, and their calcitic spicules are secreted intercellularly within an organic sheath (vs. formation of silica spicules onto an intracellularly secreted axial organic filament in Silicispongia (Botting and Butterfield, 2005)). Sponges bear only a few different cell types of which the sclerocytes produce the spicules, i.e., siliceous structures, which are often needle-shaped. These spicules often form a distinct skeleton, but occasionally they are loosely distributed throughout the sponge body without identifiable order or they are lacking entirely. Size, type, shape, combination of spicules, and their skeletal arrangements are the fundamentals of current sponge systematics (Erpenbeck et al., 2006; Boury-Esnault and Rutzler, 1997).

Among the siliceous sponges most important are the monophyletic class Hexactinellida, and the polyphyletic “Lithistida,” which includes taxa belonging to different groups within the class Demospongiae. Both classes are characterized by rigid skeletons of fused spicules.

Among the class Hexactinellida, the order Hexactinosida (subclass Hexasterophora) (Schulze, 1886), known since the late Devonian (Rigby et al., 1981, 2001), developed a rigid and, to a certain extent, firm skeleton that consists of fused hexactins. This fused, three-dimensional, generally right-angled skeletal network stays intact even after the death of the sponge.

Hexactinellida

Hexactinellida Schmidt (Porifera) are deep-water marine sponges defined by their production of siliceous spicules of hexactinic, triaxonic (cubic) symmetry, or shapes clearly derived from such forms by reduction of primary rays or terminal branches added to the ends of primary rays. They lack calcareous minerals and sclerified organic spongin as skeletal components. Siliceous spicules may be entirely loose, or partially fused to form a rigid basal and choanosomal framework. Their living tissues are mainly syncytial, with distinctive porous plugs joining differentiated regions of the syncytium to each other or to discrete cellular components. Flagellated-collar units are anucleate. Hexactinellids are viviparous and, from detailed study of a single species, produce distinctive trichimella larvae. Two subclasses are recognized by different microsclere forms – amphidiscs and hexasters.

Silica Biomineralization, Sponges, Figure 1 Specimens of glass sponge *Hyalonema* (*Corynonema*) *populiferum* Schulze, 1899 recently collected in Pacific (Oregon, USA) (a) possess high flexible anchoring siliceous spicules (b).

Hexactinellids include more than 500 described species, 7% of all Porifera, distributed in five orders, 17 families, and 118 genera (Schulze 1886, 1904; Sollas, 1888, Okada, 1928; Reischwig, 1971, 2002; Lévi et al., 1989; Mehl, 1992; Leys, 2003).

The taxonomy of the class Hexactinellida is very incomplete in the sense that probably not even half of its species are known to science. This is obvious from the fact that many of the hexactinellids species collected during recent deep-sea expeditions are new. The spicules of most hexactinellids are larger (Figure 1) and more luxuriously architected than those in demosponges (Tabachnick, 2002).

Demospongiae

In demosponges (Demospongiae Sollas, 1885) we have much the largest group, with 95% of all extant sponges. They are also the most diverse group. Some are freshwater but predominantly they are marine species living from the intertidal to the deepest seas, with around 15 orders, 88 families, and about 500 valid genera (Hooper and van Soest, 2002). The skeleton is composed of monaxononic or

tetragononic siliceous spicules (never triaxononic) bound together with collagen-like protein spongin in discrete fibers or loosely aggregated and ubiquitous collagenous filaments forming the ground substance of the intercellular matrix.

Because the morphology of the spicules differs species-specifically, they are used as a major taxonomic character. However, very little is known about the molecular mechanism(s) that determine the position and arrangement of the spicules within the demosponge skeleton (Uriz et al., 2003; Uriz, 2006).

Lithistid demosponges

Like hexactinellid sponges, lithistid sponges also contain siliceous skeletons comprising spicules. These spicules (desmas) interlock, rendering the skeleton rigid and often stony (Pisera, 2000, 2003; Kelly, 2000, 2003). At present little is known about the deposition of silica within this taxonomic order.

Lithistid sponges are commonly found on tropical and temperate seamounts and continental margins down to depths of about 1,000 m (Kelly, 2000). Several Southwest Pacific species, form large cups, bowls, and plates that extend linearly from the sponge margin. Close inspection of the lamellae show irregular or concentric ridges, indicating that silica deposition is not continuous but rather variable in nature (Ellwood et al., 2007) presented detailed records of trace metals and carbon isotopes to understand siliceous spicule formation in the deep-sea lithistid sponge *Corallistes undulatus* Lévi and Lévi, 1983 (Demospongiae: Corallistidae). X-ray analysis of two longitudinal sections removed from the lamellae of the cup-shaped sponge revealed 144 and 137 light and dark density band-pairs, respectively, within the siliceous skeleton. Although there was some variability in the ^{32}Si data, the overall age established using these data indicated that the sponge was between 135- and 160-year old.

Forms of the silica deposition in sponges

Spicules, skeletal frameworks and desmas are the main forms of the silica deposition in sponges as shown in Figure 2.

The history of the discoveries related to sponge spicules is well reviewed by Vosmaer and Wijsman (1905). According to these authors, after Schweigger in 1819 had demonstrated that the spicules of sponges in some cases do not consist of calcium carbonate, Grant in 1826 found them to contain silica, and Bowerbank in 1841 showed that, in addition to the silica some organic matter is present. Sollas in 1885 likewise finds that the sponge silica resembles opal. He states in general that the refractive index of sponge silica is that of opal or colloidal silica, and not of quartz. This kind of opal was proposed by Vosmaer and Wijsman to call *spicopal*, however, the organic matter of the spicule was called by F.E. Schulze *spiculine*. As to the structure of the spicules, Gray in 1835 had found them in *Hyalonema* glass sponge to

Silica Biomineralization, Sponges, Figure 2 SEM images of three main forms of the silica deposition in sponges: (a) spicules of demosponge *Suberites domuncula*; (b) skeletal silica-chitin-based framework of *Farrea occa* glass sponge (both images courtesy C. Ekkert), (c) siliceous desmas of *Neopelta* sp. lithistid demosponge. (Image courtesy A. Pisera.)

consist of layers, which became conspicuous by heating. These layers concentrically surround a “central canal,” which is filled out, as Kölliker in 1864 has shown, by an organic mass, the axial rod. Claus in 1868 found that the

Silica Biomineralization, Sponges, Silica Biomineralization, Sponges, Figure 3 SEM images of the axial rod (axial filament) of demosponge *S. domuncula* (a) show interconnections between individual proteinaceous nanofibrils (b) visible only at high magnification.

silica which directly surrounds this central rod, is homogenous. He called this homogenous cylinder the axial cylinder. The sponge spicule thus consists of a central organic axis, surrounded by concentric layers of opal, the outermost of which is invested in a spicule sheath of organic matter or rather of organic matter in intimate association with silica (Vosmaer and Wijsman, 1905) (Figure 3).

Using the freshwater sponge *Ephydatia fluviatilis*, Weissenfels and Landschoff (1977) and Weissenfels (1989) demonstrated that the formation of spicules starts in sclerocytes within a specific vesicle. After the production of an axial organic filament, silicon is deposited around it and the whole process of forming a spicule (190 µm in length and 6–8 µm in diameter) is completed after 40 h, at 21°C.

Siliceous sponge spicules have traditionally been separated into two categories termed, according to their size, megascleres and microscleres (Lévi, 1973). They are highly diverse in sponges and the selection pressures responsible are difficult to envisage. There are over 12 basic types of megasclere and 25 types of microsclere reported in Demospongiae, 20 basic types of megasclere, and 24 types of microsclere in

Hexactinellida, besides a long list of variations of the basic types (Lévi, 1973, 1993; Garrone et al., 1981; Simpson 1984, 1990; De Vos et al., 1991; Bavestrello et al., 1993; Boury-Esnault and Rutzler, 1997; Tabachnick and Reiswig, 2002).

Desmas differ from typical demosponge spicules: first they are joined by articulation; second, they always display irregularity and often complex morphology and sculpture. The most basic difference, perhaps, is in the fact that the crepis or axial filament is usually very short (or even invisible) and extends only a short distance from the spicule center. Growth ceases very rapidly, and an important part of a desma, including secondary branches as well as elements of sculptures, does not depend on the axial filament (Sollas, 1888; Lévi, 1991).

In contrast to the high diversity of spicules, there are relatively few basic types of skeletal framework in demosponges. Six elemental types of skeletons with intermediate forms can be differentiated: hymedesmoid, plumose, axial, radiate, reticulate, and arranged in strength confusion (Boury-Esnault and Rutzler, 1997)

Chemistry of sponge silica

It is established that siliceous sponge spicules of both the Hexactinellida and Demospongiae consist of hydrated amorphous silica (Simpson, 1989; Uriz et al., 2003; Uriz, 2003, 2006). Chemically, they differ only slightly in their $\text{SiO}_2\text{:H}_2\text{O}$ proportions. Desma bearing demosponges ("Lithistida") have a ratio of 5:1 whereas Hexactinellida have 4:1 (Hartman, 1981). Holzhüter et al. (2005) reported that spicules of demosponge *Suberites domuncula* consist of more than 90% silicon and oxygen. They found that at the molecular level silica of sponge spicules has following amorphous structure: SiO_4 tetrahedra are connected to form polyhedra, which are comparable with those found in silica gels. These polyhedra form silica particles up to 3 nm in size which are interconnected forming a dense packing containing pores. However, recently Mugnaioli et al. (2009) reported for the first time crystalline nanorod-like structures which were localized within the organic axial filament of the primordial spicules of demosponge *S. domuncula*. These nanorods have a layered structure that matches smectitic phyllosilicates. It was suggested that this kind of crystalline structure acts as an inorganic template and gives shape and orientation to the newly forming spicule, although its function is admittedly not yet fully understood.

The major trace elements found in the spicules and siliceous sponge skeletons (i.e., S, Ca, K, Na, and Cl) are also the most common in seawater (Sandford, 2003). It was suggested (Aizenberg et al., 2004) that sodium can play an important role in physicochemical properties of glass sponge spicular formations (Figure 4).

Mechanisms of silicification in sponges

Silica deposition is a fundamental process in sponges. According to the modern point of view, two different

Silica Biomineralization, Sponges, Figure 4 SEM image and EDX carbon map (a) of microtome-cut spicule of *Euplectella aspergillum* glass sponge cross section highlights the presence of an organic filament. (b) EDX Na map indicates an enhanced concentration of Na ions within the spicule cross section, with the highest density of Na occurring in the 2- μm core. (Images courtesy J. Aizenberg.)

mechanisms of silicification in sponges are proposed: enzymatic (silicatein-based) and nonenzymatic, or self-assembling (chitin- and collagen-based).

Silicatein-based silicification

The group of Morse (Shimizu et al., 1998; Cha et al., 1999; Shimizu and Morse, 2000; Weaver and Morse, 2003; Weaver et al., 2003) discovered that organic filament in demosponge *Tethya aurantium* is composed of a cathepsin L related enzyme, termed silicatein. They cloned two of the proposed three isoforms of silicateins, the α - and β -forms, from this demosponge (Cha et al., 1999). In subsequent years these molecules were cloned also from other sponges, among them *S. domuncula* and *Lubomirskia baicalensis* (as reviewed in Müller, 2003; Müller et al., 2007). The spicules are produced in special cells, the sclerocytes; that formation starts intracellularly around a silicatein filament and is completed extracellularly by apposition of silicatein onto the growing spicules (Müller et al., 2005, 2006). Cathepsin L is an endopeptidase which cleaves peptide bonds with hydrophobic amino acid residues in P2 and P3 positions and occurs in lysosomes as well as extracellularly as secreted enzymes. The silicateins are distinguished from the cathepsins by the replacement of the first amino acid residue in the catalytic triad, cysteine by serine (Shimizu et al., 1998). It has been proposed that serine increases the nucleophilicity during the nucleophilic attack at the silicon atom. The polymerization-promoting activity of the silicateins has been shown to be catalytic and not stoichiometric. It is possible that the controlled punctuated secretion of low

Silica Biomineralization, Sponges, Figure 5 The chemical mechanism proposed by Fairhead et al. (2008) to operate for the polymerization of silicic acid using silicatein molecules. The authors proposed H163 deprotonates Si(OH)_4 ; the extensive water network could permit proton shuttling. They illustrated one possibility.

concentrations of monomeric silicateins, pulses in the transitory flux of silica-precursor molecules, oscillations in the pH, ionic, or other conditions of the condensation environment, or a combination of these factors may be responsible for the annular patterning and continued deposition of silica in spicule biosynthesis in vivo once the axial filament has become completely covered during the early stages of silica deposition around this proteinaceous core. Alternatively, the continued growth of silica may be a result of dangling bonds at the growth surface of the newly deposited silica (Saito et al., 1995).

There are two possible mechanisms for enzyme catalysis (Fairhead et al., 2008): (1) stabilize at the active site one molecule of deprotonated silicic acid (the nucleophile) which will then react with another molecule of silicic acid; or (2) stabilize a protonated silicic acid (the electrophile) which will then react with another molecule of silicic acid. In proposed mechanism (Figure 5) (Fairhead et al., 2008), the roles of C25S location and flanking mutations are simply to create a sufficiently sized pocket that will allow recognition of the tetrahedral Si(OH)_4 molecule in such a way that H163 location can deprotonate it. The deprotonated Si(OH)_4 protein complex can be thought of as a template for condensation reaction. In this proposal, there is no need to involve a high energy covalent intermediate. The presence of a specific Si(OH)_4 transporter in sponge suggests the true substrate in vivo is indeed silicic acid, not high energy silicon alkoxides. This being so, the simple acid–base activation mechanism proposed by authors seems a good model for the biological process.

According to Müller et al., formation of spicules is a biologically controlled extracellular process (Schröder et al., 2006; Müller et al., 2007). The following model of silicification in demosponges is derived from observations and propositions put forth by Morse's and Müller's groups (reviewed in Leys et al., 2007). Sclerocytes secrete axial filaments composed mainly of silicateins but other organic

molecules are included. Silicatein acts as a structural template for formation of the highly organized mesoporous axial filament. Silicate is used or is actively taken up into the sclerocyte and complexed with specific proteins to form an as yet unidentified organic-silica substrate. The organo-silica complex is transported across silicalemma to the "silica deposition space." Silica from organo-silica substrate is polymerized on the outer surface of the mesoporous axial filaments as nanospheres, perhaps at serine and histidine catalytic centre sites, and the complexing protein is released and possibly recycled to the sclerocyte cytoplasm.

Growth of the axial filament continues at spicule tips, providing primary patterning of the spicule, while at the same time transport and deposition of silica continue on lateral spicule surfaces between the tips. Once the first few layers of silica nanospheres encase the axial filament, enzymatic activity can no longer be expressed by silicateins of the axial filament. Continuing deposition of silica on the outer surface of spicules is facilitated and controlled by silicatein at active sites on the silicalemma, resulting in production of specific patterned morphologies of spicules. Several elements of this model remain unverified. Other unknowns include the roles of the minor non-silicatein organic compounds incorporated in axial filaments, whether silicateins associated with the silicalemma are the same forms as those in the axial filaments and how the final high-fidelity submicroscopic external patterning on spicule surfaces is genetically controlled. However, recently Kozhemyako et al. (2009) identified silicatein genes (*AcSilA* and *AcSilB*) in nonspicule-forming marine sponge *Acanthodendrilla* spp. The authors suggest that silicateins could participate also in the functions unrelated to spiculogenesis.

Chitin- and collagen-based silicification

Aminopolysaccharide chitin has a nanofibrous structure and the chain of pyranose ring arranges almost parallel to the (100) plane and extends along the fiber axis (Iijima and Moriwaki, 1990). The chitin molecule has C=O, O–H, and N–H groups and oxygen atoms, which have affinity to the calcium, phosphate, carbonate, and hydroxyl ions of corresponding calcium phases. However, the same functional groups possess affinity to silicate ions. Because there is a possibility that such an oriented organic matrix acts as a template, or an ordered structural framework, it was hypothesized the existence of naturally occurring silica-chitin composites (Ehrlich et al., 2007). Moreover, silicon was found associated with glycosaminoglycans bound as an ether or ester-like silicate with C–O–Si or C–O–Si–O–Si–O–C bonds, in amounts of one Si atom/130–280 repeating units of the organic (Schwartz, 1973). The role of chitin in biosilicification is still not completely understood. Although chitin is one of the most important biopolymers in nature, knowledge of its interaction with silicon in vivo was absent up to now. Only recently, Ehrlich et al., isolated and identified

chitin from skeletal formations of some marine glass sponges for the first time. The presence of chitin within the framework skeleton of *Farrea occa* (Ehrlich et al., 2007) and *Euplectella aspergillum* (Ehrlich and Worch, 2007a) as well as separate spicules *Rossella fibulata* (Ehrlich et al., 2008c) could also be revealed by gentle NaOH-based desilicification technique established by Ehrlich et al. (2006) and Ehrlich and Worch, (2007b). The structure of the chitin extracted from these sponges turned out to be similar to alpha-chitin from invertebrates.

It was suggested that silicate ions and silica oligomers preferentially interact with glycopyranose rings exposed at the chitin surface, presumably by polar and H-bonding interactions (Ehrlich et al., 2008b). On the basis of the obtained results, authors proposed a model for the nanostructure of the naturally occurring silica-chitin composite unit, including interaction between poly-N-acetylglucosamine fragment of the chitin nanofibril and silica nanoparticles, which can be seen in Figure 6.

Because chitin could play a crucial role also in biosilicification in fungi (Kolb et al., 2004), it was hypothesized (Ehrlich et al., 2007) that chitin molecules are probably part of a very old organic template system involved in a biosilicification phenomenon, which was established a long time before the origin of first metazoan (e.g., glass sponges).

Recently, Ehrlich et al. reported for the first time on example of *Hyalonema sieboldi* glass sponge that its spicules are a biocomposite containing a silicified collagen matrix, and that high collagen content is the origin of the unique mechanical flexibility of the spicules (Ehrlich et al., 2006; Ehrlich and Worch, 2007b). Especially, interest is paid now to newly discovered highly hydroxylated collagen isolated from *H. sieboldi* spicules (Prof. M. Collins personal communication). Glass sponges are largely restricted to deep, cold-water (between 0 and 4°C) habitats (Tabachnick, 1991; Janussen et al., 2004; Dohrmann et al., 2008). Therefore, from the ecological point of view collagen- (as well as chitin-) based silicification which occurs in spicules and other skeletal formations of these sponges is an example of unique cold-water biomineralization. There is no evidence in the literature about silicatein activities at this temperature level. Skeletal biomineralization requires energy and so imposes a metabolic cost on skeleton-forming organisms (Knoll, 2003). The hypothesis is that probably some phosphate moieties and ATPase-based mechanisms are in some way involved in biosilicification at temperatures near zero (Ehrlich, 2009).

The procedure of alkali slow etching opens the possibility to observe the forms of collagen fibrils located within silica layers of sponge spicules and their distribution. For example, the results obtained by SEM observations of the desilicified spicular layers of *Monorhaphis chuni* provide strong evidence that collagen fibrils' orientation within spicules possesses twisted plywood architecture (Ehrlich et al., 2008b). Typical fibrillar formations were observed within the tubular silica structures of this sponge in all layers starting from the inner axial channel

containing axial filament (Figure 7c) up to the outermost surface layer of the spicules as shown in Figure 7b and Figure 7d. The fibrils in each cylinder form individual concentric 2D networks with the curvature of the corresponding silicate layers. These layers of about 1 µm in thickness are connected among each other by protein fibers (Figure 7a), which possess a characteristic nanofibrillar organization. Partially desilicified nanofibrillar organic matrix observed on the surface of silica-based inner layers of the demineralized spicule provides strong evidence that silica nanoparticles of diameter about 35 nm are localized on the surface of corresponding nanofibrils (Ehrlich et al., 2008b). This kind of silica nanodistribution is very similar to the silica distribution on the surface of collagen fibrils in the form of nanopearl necklets, firstly observed in the glass sponge *H. sieboldi* (Ehrlich et al., 2006; Ehrlich and Worch, 2007b). It was suggested that the nanomorphology of silica on proteinous structures described above could be determined as an example of biodirected epitaxial nanodistribution of the amorphous silica phase on oriented collagenous fibrillar templates (Ehrlich et al., 2008b). From this point of view, basal spicules of *Monorhaphis* sponges could be also defined as natural plywood-like silica-ceramics organized similarly to the crossed-lamellar layers of seashells. The authors suggested also that the matrix of the *M. chuni* anchoring spicule is silicified fibrillar collagen rather than collagen-containing silica which is the reason for their remarkable mechanical flexibility.

Biogeological aspects of silica deposition by sponges

Analysis of the biogeochemical cycle of silicon suggests that the biospheric environmental silicic acid concentration may have varied considerably during the time of life on Earth. Biochemical evolution today is proceeding within environments in which the silicic acid concentration is considerably lower than previous evolutionary periods (Exley, 1998).

Concomitant with the advent of dioxygen, about 2500 million years ago, and its subsequent gradual increase in atmospheric concentration from approximately 1% towards the level of 20% which is characteristic of today, there occurred an increasing number of organisms within which silicic acid was processed to silica. The most important of these, in the terms of their diversity, ubiquity (both freshwater and marine species) and biomass, were the diatoms, which occur however late in earth history (Mesozoic). The diatoms are characterized by a silica frustule which surrounds their cell wall. Interestingly that chitin-based organic networks are an integral part of cell wall biosilica from the diatom *Thalassiosira pseudonana* (Brunner et al., 2009). According to Maldonado et al. (2005), our current understanding of the silicon cycle in the ocean assumes that diatoms dominate not only the uptake of silicic acid, but also the production and

Silica Biomineralization, Sponges, Figure 6 Proposed model (adapted from Ehrlich et al., 2008c) of nanostructural organization of the naturally occurring silica-chitin composite unit (a) isolated from spicules of *Rossella fibulata* glass sponge. Silica nanoparticles tightly surround chitinous nanofibrils (b) Schematic view (c) shows a possible nanodistribution of silica on the surface of chitinous nanofibril. Image (d) represents the hypothetical scheme of interaction between silica and poly-N-acetylglucosamine-fragment of the chitin nanofibril and formation of the corresponding hydrogen bonds.

Silica Biomineralization, Sponges, Figure 7 Proposed model (c) of micro- and nanostructural organisation of the basal spicule of *Monorhaphis chuni* glass sponge with respect to organic matrix. Collagen nets, surrounding the spicules, showed a tight mat of nanofibrils (b, image courtesy C. Eckert). SEM image (a) shows a collagenous fibrillar matrix which could function as glue between concentric layers. Schematic image (c) represents the region of the axial canal and axial filament. The axial canal of *M. chuni* possesses a characteristic quadratic opening and contains oriented bundles of unsilicified collagenous nanofibrils. The base material of the walls of the axial canal and concentric layers distributed above it consists of silicified collagen fibrils with a twisted plywood orientation (d). This kind of fibrillar architecture could be responsible for the remarkable micromechanical properties of the spicule as a biocomposite made by silica and collagen.

recycling of biogenic silica, and that other organisms with siliceous skeletons, including sponges, radiolarians, and silicoflagellates, play a negligible role. The authors showed that the retention of Si by siliceous sponges in some sublittoral and bathyal environments is substantial and that sponge populations function as Si sinks. Therefore, sponges may affect Si cycling dynamics and Si availability for diatoms, particularly in Si-depleted environments. It was strongly suggested (Maldonado et al., 2005) that the role of sponges in the benthopelagic coupling of the Si cycle is significant. For example, Antarctic giant hexactinellids, such as *Rossella nuda* and *Scolymastra joubini*, which may be up to 2 m tall, 1.4 m in diameter, and up to 600 kg wet weight, containing up to 50 kg biogenic silica each (Maldonado et al., 2005). They are extremely slow-growing and seemingly reproduce only at long time intervals (Dayton et al., 1974) and become old, probably more than 1,500 years (Dayton, 1979; Gatti, 2002). While their living tissues represent only a modest biomass, the silicious spicules of hexactinellids become an important ecological factor. After the death of the sponges, the megascleres do not dissolve but accumulate on the bottom and over large areas to form spicule mats commonly about 50 cm thick but occasionally exceeding 2 m (Koltun, 1968; Dayton et al., 1974; Henrich et al., 1992). The mats structure the fauna living in and on them.

Marine sponges fractionate silicon isotopes during opal biomineralization to a greater degree than any other process on Earth thus far investigated (De La Rocha, 2003). This ability is in keeping with both their extremely negative silicon isotope composition and their inefficient uptake of silicic acid relative to other silicon-biomineralizing organisms.

Sponges seem to be important players in numerous geobiological processes (Reitner, 2004). For example, siliceous sponge reefs had a wide distribution in prehistoric times and once constructed the largest reefs known on earth, reaching an acme in the Upper Jurassic when a deep-water reef belt on the northern Tethys shelf existed that was 7,000-km long (Krautter et al., 2001). In present times hexactinellid sponges of the order Hexactinosida have constructed reefs at several localities off the coast of British Columbia, Canada. The reefs occur on relict glaciated seafloor areas with a low sedimentation rate and a high dissolved silica concentration in the Queen Charlotte Basin and in Georgia Basin (Conway et al., 2004, 2005) and the reefs represent stable communities that have been growing for up to 9,000 years. The main framebuilders include the hexactinosidan species *Aphrocallistes vastus*, *F. occa* and *Heterochone calyx* in Queen Charlotte Basin, and *A. vastus* and *H. calyx* in Georgia Basin (Conway et al., 2004). The framework of these reefs is constructed through several processes of framebuilding, and the reef matrix is derived from trapping of suspended sediments (Krautter et al., 2001). Similar framebuilding processes are thought to have contributed to the formation of the ancient reefs (Krautter

et al., 2006). Upwelling and downwelling oceanographic processes in a biologically productive coastal sea have contributed to the development of large reef complexes. The reefs form as bioherms (mounds) and biostromes (beds or sheets) that may rise up to 21 m above the seafloor and they cover around 1000 km² on the continental shelf. Individual reef complexes may cover areas of more than 300 km² and occur in 90–240 m depth range (Conway et al., 2001, 2005; Lehnert et al., 2005). Trapping fine-grained siliciclastic sediments in suspension in near-bottom currents is an important part of the mound-forming process, as it prevents the reef framework from collapsing under its own increasing weight.

Summary

Sponges are exclusively aquatic, sedentary, filter-feeding invertebrates, producing silica-made skeletons consisting of individualized elements (spicules) of lengths ranging from micrometers to centimeters, which can subsequently fuse or interlock with each other. The high diversity of spicule shapes and sizes in both fossil and living sponges has been repeatedly reported in literature. However, the mechanisms that determined such diversity remained elusive until recently. We are beginning to understand the mechanisms of spicule secretion and formation and the role of spicules and skeletal frameworks in the biogeology.

Molecular techniques and ecological experiments have demonstrated the genetic control of the process and the contribution of environmental factors to the expression of a sponge spicule, respectively. Silicatein proteins govern the enzymatic and structurally controlled synthesis of silica in marine demosponges. However, new biomineralization topics such as the role of chitin and/or collagen as self-assembling and nanofibrillar organized templates in sponge related biosilicification phenomena require further investigation.

SILICOFLAGELLATES

Silicoflagellates are planktonic, microscopic algae with siliceous skeletons, characterized by their simple geometries and remarkable variability. Taxonomically, they belong to different classes of the Stramenopiles and possess complex plastids derived from secondary endosymbiosis (see entry [Symbiosis](#)). Silicoflagellate skeletons may have considerable potential as environmental indicators and are common in fossil deposits, dating back to the middle Cretaceous (ca. 120 Ma), with species diversity reaching a peak in the Miocene (ca. 23–25 Ma). Today, only a single genus *Dictyocha* with approximately five recognized species exists. For more details, please refer to entry ["Algae \(Eukaryotic\)"](#).

SOM. Soluble organic matrix

IOM. Insoluble organic matrix

GRN. Gene regulatory network

Introduction

One of the major events in the evolution of multicellular animals was the transition from soft-bodied organisms to those that possessed mineralized hard parts for protection

and support. This major evolutionary hallmark supported the rapid diversification of animals and their occupation of a diverse range of novel ecological niches at the dawn of the Phanerozoic, between 560 and 530 million years ago, when mineralized skeletons appeared relatively synchronous in a variety of Phyla during the so-called Cambrian Explosion (Knoll, 2003; Conway Morris, 2006). However, it is still unclear exactly what drove this sudden capacity to construct mineralized structures, be it changes in ocean chemistry (Brennan et al., 2004) or the evolution of more diverse ecologies (Cohen, 2005), including predators (Vermeij, 1989). Investigation of biomineralization processes will provide insight into the molecular and genetic mechanisms that accompanied the appearance of mineralized body parts during the early Cambrian, shedding light on the processes that generate the diversity of life we see around us today.

Until recently, studies of biomineralization processes were mainly restricted to describing the (ultra)structure of the minerals and their interaction with the organic material provided by the organism (Lowenstam and Weiner, 1989; Mann and Webb, 1989). However, the generation and elaboration of biominerals is ultimately controlled by genes (Jackson et al., 2006, 2007a, b), which must in turn be expressed in the appropriate tissue and at an appropriate stage of development. Understanding the evolution of such biomineralizing genes and the gene regulatory networks (GRNs) in which they act is, therefore, vital to the understanding of how animals evolved and will also provide clues for the fabrication of biomimetic materials.

Biomineralization

Biomineralization refers to the processes by which organisms form minerals (e.g., calcium carbonate, calcium phosphate, silica, iron oxides) under strict biological control. These processes are, therefore, defined as *biologically controlled mineralization*, with the skeletons formed being integral, functional parts of the organisms (Lowenstam and Weiner, 1989). There are, however, several other serendipitous processes linked to living organisms (e.g., microbes) or organic substances that result in mineral (mainly calcium carbonate) formation that are not under strict control of organisms. These processes are termed either *biologically induced mineralization*, where inorganic minerals are precipitated by adventitious precipitation resulting from secondary interactions between various metabolic processes and the surrounding environment (Mann, 2001), or *organomineralization*, a term used to describe mineralization processes that involve organic molecules or particles, whether linked to living organisms or not (e.g., degrading organic matter) (Trichet and Defarge, 1995).

While both *biologically induced* and *organomineralization* play an important role in the formation of carbonate systems in the geological record (e.g., microbialites, stromatolites, ooids) (Reitner and Neuweiler, 1995; Arp,

1999; Reitner et al., 2000), it is *biologically controlled mineralization* that is responsible for the production of sophisticated biomaterials such as bones, shells, and teeth, some of which show exceptional strength and beauty, often of high commercial value (i.e., pearls).

Biologically controlled mineralization almost always has organic macromolecules associated with the process of mineral formation, which can comprise up to 5% of the total mass of a biomineral and fulfill important functions during initial crystal nucleation, crystal growth, and growth termination, as well as contributing to the biomechanical properties of the mature product (Simkiss, 1986; Simkiss and Wilbur, 1989). Following the removal of the mineral itself, these organic macromolecules are often subclassified as being either water soluble organic matrices (SOMs), or water insoluble organic matrices (IOMs). IOMs are largely neutrally charged, often highly polymerized, and act as frame building matrices akin to collagen, chitin, or silk proteins (Yan et al., 2007; Yano et al., 2007). SOMs are often highly acidic, due to negatively charged carboxylate groups, are typically rich in aspartic acid (asp) and/or glutamic acid (glu), and usually have mean molecular weight of 10–30 kDa (Bédouet et al., 2001, 2006).

While organic macromolecules appear ubiquitous and pivotal in *biologically controlled* biomineralization (with the focus here on biocalcification), an increasing number of studies now show that a transient amorphous (noncrystalline) phase of calcium carbonate (ACC) is frequently involved in the formation of the earliest stages of calcium carbonate biominerals (Aizenberg et al., 2003; Politi et al., 2004; Weiner and Dove, 2003). However, little is known about the ACC as well as the organic macromolecules involved in calcification in most animal taxa.

Several SOM proteins have been sequenced and characterized, mainly in sea urchins, mollusks, and vertebrates (Treccani et al., 2003; Wilt et al., 2003). About 45 soluble proteins were detected by 2D gel electrophoresis in demineralized spicules from the embryo of the sea urchin *Strongylocentrotus purpuratus* (Killian and Wilt, 1996). Several of these proteins were later cloned and sequenced (e.g., SM27, SM30, SM50) (Zhu et al., 2001) and their role and function in the biomineralization process confirmed by immunohistochemical methods (Ameye et al., 1999; Urry et al., 2000), in situ hybridization (Illies et al., 2002), or by using antisense oligonucleotides directed against spicule matrix proteins (Peled-Kamar et al., 2002). All of the cloned spicule matrix proteins of *Strongylocentrotus* share as common features a C-type lectin domain and proline rich repeat regions. Furthermore, the first 35 amino acids of SpSM32 and SM50 are identical, probably representing splicing variants of the same transcript, although this has yet to be confirmed (Wilt et al., 2003). The precise functions of any of these proteins are unknown (Wilt et al., 2003) and their evolutionary origin and relationships remain largely unresolved (but see Bottjer et al., 2006). An increasing number of reports are, however, elucidating the functional roles of various biomineralizing proteins. For example, the starmaker

protein is known to influence crystal size and lattice formation in otolith biomineralization (Söllner et al., 2003), while the nacre protein perlucin (Mann et al., 2000; Weiss et al., 2000) is known to nucleate the growth of aragonitic calcium carbonate crystals (Blank et al., 2003).

Identification and characterization of the genes directly involved in the process of biocalcification, and the ways in which these “structural genes” are regulated, is essential for our understanding of the evolution of metazoan biocalcification. One of the most advanced systems currently used to study the complexity of the GRNs involved in specifying biomineralizing cell types is the sea urchin. The manipulability of urchin embryos and the availability of a high-quality genome sequence have allowed researchers to identify specific transcription factors (genes that activate the expression of target genes) that activate biomineralizing genes and proteins (Ettensohn et al., 2003, 2007). Furthermore, recent work has identified the nodes in biomineralizing GRNs that are responsible for specifying cells involved in larval skeletogenesis and adult skeletogenesis (Gao and Davidson, 2008), providing insight into the evolution of the metazoan biphasic lifecycle. Such endeavors are also highly relevant to issues of global climate change and ocean acidification – by assessing how resilient marine calcifying organisms are to fluctuations in ocean chemistry, highly species-rich marine ecosystems such as coral reefs may be effectively managed.

The evolution of biocalcification

In the geological record, major animal phyla began biomineralizing shortly before, or during, the so-called Cambrian Explosion, about 530 million years ago, when a highly diverse group of animals appeared suddenly in the fossil record (Knoll, 2003). As most of these phyla are thought to have diverged well before this biomineralization event (Peterson et al., 2008), various causes for this relatively synchronous adoption of biomineralizing strategies have been postulated and remain an area of continuing debate. These include the evolutionary driving force of predation (Vermeij, 1989) or the result of a response to changes in ocean chemistry with greater than previous levels of calcium, requiring the need for effective cellular calcium-detoxification mechanisms (Degens et al., 1985; Kazmierczak et al., 1985).

The vast majority of newly appearing biomineral products in the Cambrian was based on calcium (either as calcium carbonate or calcium phosphate) (Lowenstam and Margulis, 1980). Precise control of intracellular calcium levels is necessary for the formation of microtubules which are needed by eukaryotic cells. Based on this, Lowenstam and Margulis suggested that calcium regulation and transport systems in the late Precambrian metazoans provided the evolutionary prerequisites for their eventual use in biomineralization. CaCO_3 biomineral formation can be useful for the organism because this process allows the elimination of a cell-toxic surplus of Ca^{2+} through enzymes such as calmodulin and membrane

bound Ca^{2+} -ATPase, which directly transports calcium to loci where it is used as a physiological control factor (Degens, 1979).

The question of whether the ability to biocalcify evolved several times independently among various animal groups, possibly to produce armor in response to increased pressure from predators (Marshall, 2006), or whether preexisting calcium regulation and transport systems in the late Precambrian metazoans provided the evolutionary prerequisites for their eventual use in biomineralization (Lowenstam and Margulis, 1980), still remains open to debate. If calcium carbonate biomineralization evolved as a physiological response (mutual to many taxa) to increasing calcium levels in the late Precambrian ocean, then an evolutionary link between the proteins and the regulatory elements involved in skeletogenesis can be postulated among metazoan groups. This evolutionary connection could either be due to massive horizontal gene transfer in ancestral Precambrian organisms or as a result of the exaptation of a preexisting genetic makeup into a new role (biocalcification) in many disparate animal lineages (Kirschvink and Hagadorn, 2000). The latter leads to the hypothesis that the last common ancestor of the metazoa (LCAM) provided a “genetic biomineralization toolkit,” a core set of conserved biomineralization genes to regulate and initiate the cellular functions required for the assembly of calcium carbonate biominerals (Ca^{2+} , HCO_3^-). Subsequently, this core gene cassette and associated regulatory elements have been elaborated upon to produce the range of biomineralized structures we observe in the Earth’s history. One major process by which complex biological systems evolve is by taking an existing genetic pattern evolved for a certain function, duplicating it, and adapting it for a new role (e.g., Carroll et al., 2001). The nascent system is gradually debugged and improved through the process of random mutation and natural selection. This powerful hypothesis, in the context of biomineralization, still awaits an expanded program of comparative geobiological research (Knoll, 2003).

However, evidence for conserved biocalcification mechanisms is beginning to emerge. Some homologies between certain molluscan (Weiss et al., 2001) or sea urchin (Ettensohn et al., 2003) and vertebrate matrix proteins have already been postulated. Ettensohn et al. (2003), for example, found homologies of their sea urchin Sp/LvAlx1 protein, which is an essential component of the gene network that controls downstream genes required for biomineralization, with members of the vertebrate Cart1/Alx3/Alx4 protein family. Members of this gene family have been implicated to be instrumental in the formation of the limb skeleton and the neural crest-derived skeleton of the face and neck in vertebrates. Further, there seems to be some fundamental underlying immunological similarity between macromolecules involved in vertebrate hydroxyapatite and invertebrate aragonite formation (i.e., molluscan nacre), because freshly ground nacre did not result in an immune response when injected into human jaw bones, but in fact

stimulated bone regeneration (Marin and Westbroek, 1998; Lopez et al., 1992). Coral skeletons are already used as bone implants with a similar (albeit weaker) effect on bone regeneration (Demers et al., 2002). Although bone, nacre, and coral skeletons are not homologous structures as such, parts of the complex underlying physiological machinery that controls biomineral formation probably are – a hypothesis strongly supported by the above mentioned results. However, these homologous parts may have served a different function than biomineralization in the (nonskeletonized) common ancestor of corals, mollusks, and vertebrates, later being co-opted for producing biominerals when the necessity arose.

If, as outlined above, calcium carbonate biomineralization systems in the major metazoan phyla evolved from the core skeletogenic toolkit of the last common ancestor of animals, then ancestral metazoan systems should be used as an anchor for a paleogenomic approach to reconstruct this toolkit and explore the evolutionary road map of diversification by comparison with more derived animal taxa. Paleogenomics analyzes the genomes of contemporary taxa to reconstruct ancient genomes and genomic features and to infer the function of ancestral genes.

Recent paleogenomic studies go beyond the focus on classical matrix proteins. Expressed sequence tags (ESTs), cDNA libraries, and recently sequenced genomes have been utilized to examine the inheritance of ancestral toolkits that were involved in skeletogenesis. By using a calcifying coralline sponge of a “living fossil,” *Astrosclera willeyana*, a key component of the ancestral skeletogenic toolkit – α -carbonic anhydrase – has been identified (Jackson et al., 2007b). Duplication of this gene is likely to have allowed biocalcification to evolve in many clades of metazoans. In contrast, the recently sequenced genome of the sea urchin *Strongylocentrotus purpuratus* has revealed that genes essential for the construction of the echinoderm skeleton (the stereome) are echinoderm-specific and are likely to be the same as those in the earliest echinoderms and their direct ancestors more than 520 million years ago (Livingston et al., 2006). Similarly, in gastropods (snails; *Haliotis asinina* and *Lottia scutum*) an unexpected level of genetic novelty and complexity in the skeletogenic toolkit suggests that there are significant molecular differences in the ways in which gastropods synthesize their shells (Jackson et al., 2006). These features, along with the modular design of the molluscan mantle, contribute to the spectacular morphological and mineralogical variety we observe among contemporary mollusk shells (Jackson et al., 2007a).

From the limited data available, we can develop the following scenario as a working hypothesis (Figure 1): the last LCAM possessed a core biomineralization toolkit that at least consisted of an α -carbonic anhydrase, providing the core capacity to regulate the reversible hydration of CO_2 , necessary for biocalcification. Other, as yet undiscovered, parts of this toolkit most likely contained genes that regulate Ca^{2+} trafficking, scaffolding genes for organic matrix production, as well as regulatory

Animal Biocalcification, Evolution, Figure 1 Conceptual summary. The last common ancestor of all Metazoa (LCAM) possessed a core gene toolkit for the regulation of Ca_2^+ and an alpha-carbonic anhydrase to catalyse the reversible hydration of CO_2 . During subsequent metazoan evolution, parts of this toolkit (genes and regulatory elements) were exapted to new roles including calcium carbonate fabrication. Novel genes and biosynthetic pathways were added to the conserved biocalcification toolkit to produce the variety of skeletal forms we observe among extant animal lineages.

elements. During subsequent animal evolution, genes in this core set were duplicated in different lineages, resulting in a relatively simple genetic repertoire in basal metazoans, but in a highly diverse gene array in the various lineages of the Bilateria (Ecdysozoa, Lophotrochozoa, and Deuterostomia). A high degree of lineage-specific innovation on top of a conserved gene-set then allowed for the diversification of the numerous skeletal architectures we observe since the dawn of the Cambrian.

Conclusion

While the structural processes of biomineralization, and in particular biocalcification, are receiving vigorous attention from various international groups, a far more detailed characterization of the core ancestral skeletogenic toolkit as well as lineage specific innovations are needed before we understand how the impressive diversity and beauty of metazoan skeletal structures originated and evolved. As this knowledge is acquired, we can anticipate the construction of new high-performance biomimetic materials and the measurement and prediction of the resilience of marine calcifying organisms to rapidly changing environmental parameters, such as ocean acidification.

ANIMAL SKELETONS, ADVENT

Early biomineralization event; Small shelly fossils

Definition

Animal skeleton. Biologically, an animal skeleton is a hard or rigid framework that could provide protection and

support in many types of animals. Most of the animal skeletons are mineralized, but some of them may not be mineralized (e.g., some annelid tubes being agglutinated). They could be subdivided into exoskeletons and endoskeletons, excluding hydroskeletons. The “skeletons” of resistant organic biopolymers are not included herein.

Exoskeleton. Exoskeletons are external hard parts. They may enclose the soft tissues and organs of the body, or may be external sclerites.

Endoskeleton. Endoskeletons are internal hard parts (typical of many vertebrates). Most of the endoskeletons are generally surrounded by skin and musculature.

Small shelly fossils (SSF or SSFs). A non-taxonomic term was first used by Matthews and Missarzhevsky in the title of their review paper in 1975 to denote the earliest skeletal fossils, although some of these fossils may not be small and most of them are actually not shells. It has been popularly used in literature somewhat as a catchall term for the early Cambrian skeletal fossils, including spicules, shells, tubes, and diverse disarticulated sclerites.

Introduction

Skeletal biomineralization (skeletonization) was part of the initial diversification of early animals. The fossil record provides an important clue to the origin of biomineralization in the animal phyla (Kirschvink and Hagadorn, 2000). The earliest occurrence of animal skeletons was in the late Ediacaran, e.g., *Cloudina*, *Sinotubulites*, and *Namapoikia*, although the generic diversity was quite low and the biomineralization of these calcareous skeletons was not well controlled biologically (Grant, 1990). The early Cambrian (542–525 Ma) saw the largest burst of diversified animal skeletons, represented in the fossil record by poriferans, cnidarians, many extant bilaterian phyla, and some problematic taxa (Figure 1) (Bengtson, 2004). In terms of structural and mineralogical diversity of animal skeletons, the early Cambrian represents a quantum jump (Bengtson and Conway Morris, 1992). The abrupt advent of diversified skeletal fossils not only has been taken as a major piece of evidence for the Cambrian radiation but also was envisioned the biomineralization event. Since most of these skeletal fossils are typically small in size, and lots of them represent disarticulated sclerites and are enigmatic with respect to their biological affinities, they are commonly referred to as “small shelly fossils (SSFs)” in the literature (Matthews and Missarzhevsky, 1975; Qian, 1999). But some of the early skeletal fossils, such as the sponge-like archaeocyaths, trilobites, and bivalved arthropods, are rarely described under this nontaxonomic term, while some fossils described under the term of SSFs, such as embryo fossils and cnidarian polyps, may have been originally composed of resistant organic membranes or tubes without biomineralization, and the skeleton-like appearance is mainly due to the secondary phosphatization.

Microbial biomineral formation

Definition

Microbial biomineralization describes the formation and deposition of minerals directly mediated or indirectly influenced by microorganisms (Mann, 2001; Weiner and Dove, 2003; Ehrlich, 1999). A huge variety of minerals results from individual biomineralization pathways linked to the phylogeny and metabolic activity of the microorganisms involved (Weiner and Dove, 2003;

Minsky et al., 2002). Moreover, microbial biominerals may differ distinctly from their inorganically formed equivalents in shape, size, crystallinity, isotopic, and trace element composition (Bazylinski et al., 2007; Haferburg and Kothe, 2007; Takahashi et al., 2007; Weiner and Dove, 2003). A compilation of microbial biominerals and their source organisms is given in Table 1.

Two principal modes of microbial biomineralization processes occur, namely biologically induced mineralization (BIM) and biologically controlled mineralization

(BCM, Lowenstam, 1981; Lowenstam and Weiner, 1989). These modes are introduced in the following.

Biologically induced mineralization (BIM)

In BIM, the nucleation and growth of biominerals are extracellular processes triggered by the metabolic activity of the microorganism. Biomineralization takes place because of the changes in the chemical equilibrium of the surrounding environment and may also be linked to

For comprehensive reading, the following books are recommended: Sigel et al. (2008), Baeuerlein (2000), Banfield and Nealson (1997), Dove et al. (2003), Driessens and Verbeeck (1990), Lovely (2000), Lowenstam and Weiner (1989).

particular metabolic products. The resulting biominerals typically show a poor crystallinity, are chemically heterogeneous, and often closely associated with the cell wall (Frankel and Bazylinski, 2003). An active and a passive mineralization process can be distinguished (Fortin and Beveridge, 2000; Southam, 2000). Active mineralization refers to mineralization by (a) the direct redox conversion of specific metal ions bound to the bacterial surface or (b) the excretion of metabolically produced ions and thereby forming minerals. The term passive mineralization is used when *nonspecific* binding of cations and the involvement of surrounding anions causes nucleation and growth of minerals. Passive mineralization can even be mediated by dead cells, due to the exposure of negatively charged surfaces acting as nucleation sites for metal cations (Urrutia and Beveridge, 1993). Particularly in BIM, extracellular polymeric substances (EPS) are involved in the mineralization process (Chan et al., 2009; Ercole et al., 2007). As an example of BIM, the precipitation of iron oxyhydroxides by the iron oxidizing bacterium *Gallionella ferruginea* is displayed in Figure 1.

Biologically controlled mineralization (BCM)

BCM implies that the organism actively controls the nucleation site, growth, morphology, and final location of the mineral (Banfield and Nealson 1997; Bazylinski

Microbial Biomineralization, Figure 1 Stalk-shaped extracellular polymeric substances (EPS) produced by the iron oxidizing bacterium *Gallionella ferruginea* are heavily encrusted with iron oxyhydroxide minerals formed by biologically induced mineralization (BIM).

and Frankel, 2003). Although the modes of exerting crystallochemical control over the mineralization process may greatly vary across species, the common characteristic of BCM is that mineral formation takes place in a closed, isolated environment. While Weiner and Dove (2003) categorized BCM in *extra*-, *inter*- or *intracellular* mineralization, Mann (2001) differentiated between two key modes of BCM, namely *matrix-mediated* mineralization and *boundary-organized* mineralization. Generally speaking, extracellular mineralization corresponds to matrix-mediated mineralization, whereas inter- and intracellular mineral formation are equivalent to boundary-organized mineralization.

Extracellular BCM implies the production of a macromolecular matrix outside the cell. This matrix is typically composed of proteins, polysaccharides, or glycoproteins, forming a three dimensional framework, and the cell actively supplies cations to the matrix for an “on-site” nucleation and growth of the biomineral (Weiner and Dove, 2003).

Intercellular BCM occurs mostly in single-celled organisms, existing in a community. This type of mineral formation is not common in bacteria, but is commonly found in calcareous algae, for example, *Halimeda* (de Vrind-de Jong and de Vrind, 1997; Borowitzka, 1982).

Intracellular BCM takes place inside specific compartments within the cell, for instance vesicles or vacuoles. Thus, the organism is able to exactly regulate the chemical composition, morphological structure, and particle size of the mineral. The only bacteria known to perform intracellular BCM are magnetotactic bacteria, which use a vacuole-based system for the crystallization of magnetic biominerals (Table 1). Similar systems of intracellular

Microbial Biomineralization, Figure 2 Intracellular iron sulfide (greigite, Fe_3S_4) crystals formed by biologically controlled mineralization (BCM) within a magnetotactic bacterium. (Image courtesy of Joachim Reitner.)

BCM are only known from higher eukaryotic organisms, controlling for example, the bone and teeth formation in mammals (Kirschvink and Hagadorn, 2000). An example of microbial biominerals formed by intracellular BCM is shown in Figure 2.

MICROBIAL COMMUNITIES, STRUCTURE, AND FUNCTION

Michael W. Friedrich
 University of Bremen, Bremen, Germany

Definition

Microbial species. Microorganisms exhibiting a high degree of phenotypic and genetic similarity; a pragmatic approach to demarcating “microbial species” using molecular biology tools has been 97% 16S rRNA sequence identity or 70% genome identity based on DNA-DNA hybridization (Stackebrandt and Goebel, 1994); thus, microbial species are often defined by operational characteristics (operational taxonomic unit). The microbial species concept is still a matter of controversy.

Microbial population. Individual microorganisms (of the same “species”) form a population.

Guild. Metabolically related populations, e.g., sulfate-reducing microorganisms.

Microbial community. All microbial populations in a habitat.

Microbial community structure. The composition of a microbial community and the abundance of its members.

Microbial diversity. The number of different species in a habitat; sometimes (falsely) used as a synonym for community structure.

Habitat. The physical location or dwelling place of a particular organism, where an individual microbial eco-type can be found or isolated from.

Ecosystem. A community of microorganisms and their natural environment.

Ecological niche. Different from the habitat (spatial), the niche defines the function of an organism.

Introduction

Microorganisms are an indispensable part of the biogeochemical cycles on Earth, have the longest history in evolution, and represent the largest genetic reservoir. Mostly invisible to the naked eye, microbes represent the largest source of biomass on Earth, with an estimated number of $4\text{--}6 \times 10^{30}$ cells, and 350–550 Pg of C (1 Pg = 10^{15} g), and have colonized almost any niche available on Earth (Whitman et al., 1998). In their habitats, microorganisms usually do not exist as single, genetically identical population, but live together with other microbial populations as microbial communities carrying out important functions of an ecosystem such as primary production and remineralization of biomass.

A hallmark of microbial life is its diversity. For a long time, only little was known about the magnitude of microbial diversity, as this was based on cultivation. Only about ~7,000 noneukaryotic species have been formally described (Euzéby, 1997) (<http://www.bacterio.cict.fr/number.html>), and insects were regarded as much more diverse than microorganisms. In microbiology, the term “diversity” is often used to refer to the number of different species in a given habitat, or, when based on molecular data, refers to the number of different sequences present. Diversity reflects the types of microbes present in a habitat, but “community structure” encompasses quantitative information on the different taxa and guilds (Liesack et al., 1997). Eventually, the analysis of community structure will allow for assessing the role and importance of microbes in their habitats and ecosystems. Presently, it is still methodologically difficult to obtain a complete view of microbial diversity and community structure.

Methods of community structure analysis

Cultivation: Traditionally, the diversity of microbial communities has been studied by cultivation, i.e., by viable plate counts or most-probable-number (MPN) dilution techniques. However, the morphology of microorganisms is too simple for reliable identification and classification. Identification of microorganisms by cultivation requires pure cultures for testing physiological, biochemical, and cell biological characterization and suitable media for their growth, which is a major bottle neck. There are no cultivation media available that allow for capturing growth requirements of all microorganisms in a sample, and we often do not even know of their existence and presence. Direct microscopic counts can be of orders of magnitude higher than the counts of bacteria obtained on growth media (“plate counts”). Typically, only a small

BIOMINING (MINERAL BIOLEACHING, MINERAL BIOOXIDATION)

Douglas Eric Rawlings
 University of Stellenbosch, Matieland, South Africa

Summary

Biomining is the use of autotrophic, acidophilic, iron-, and sulfur-oxidizing microorganisms to produce ferric iron and sulfuric acid. These chemicals are capable of oxidizing a variety of minerals containing insoluble metal sulfides such as Fe₂S, CuS, NiS, and ZnS into their soluble sulfate forms e.g., Fe₂SO₄, CuSO₄, NiSO₄, and ZnSO₄, respectively, resulting in their extraction into water from which they may be more easily recovered. Metal leaching is carried out from mineral waste dumps, or more typically and especially from constructed heap or stirred tank reactors. The metals recovered commercially in the greatest quantities are copper and gold.

Description of the terms bioleaching, biooxidation, and biomining

The term *bioleaching* refers to the conversion of an insoluble metal (usually a metal sulfide, e.g., CuS, NiS, ZnS) into a soluble form (usually the metal sulfate, e.g., CuSO₄, NiSO₄, ZnSO₄). As the metal is extracted into water, this process is called bioleaching. Because this process involves oxidation, it may also be termed *biooxidation*. However, the term biooxidation usually refers to processes in which the recovery of a metal is enhanced by microbial decomposition of the mineral, but the metal being recovered is not solubilized. An example is the recovery of gold from arsenopyrite ores where the gold remains in the mineral after biooxidation and is extracted by cyanide in a subsequent step. The term bioleaching is clearly inappropriate when referring to gold recovery (although arsenic, iron, and sulfur are bioleached from

the mineral). *Biomining* is a general term that may be used to refer to both processes (Rawlings, 2002).

Definition

Biomining is a generic term that refers to a collection of biotechnological processes in which microorganisms are used in the recovery of metals from mineral ores and concentrates. The microbial processes involved are the same as those responsible for acid mine drainage, and where metals are recovered during the treatment of acid mine drainage such a process may be termed biomining. Although the bioadsorption of metals onto biological materials including microorganisms may be used in metal recovery, the term biomining has not been applied to bioadsorption processes.

Metals that are recovered in the greatest quantities in commercial processes are copper, gold, and cobalt. Illustrations of the number and scale of operations that employ microorganisms for metal recovery are to be found in Olsen et al. (2003) and Rawlings et al. (2003). Processes also exist for the treatment of nickel- and zinc-containing ores although recovery of these metals using "biomining" has not been commercialized. For several years uranium was recovered using related processes (McCready, 1988) and the technology has the potential for the recovery of several other types of metals. In general, to be amenable to biologically assisted leaching, the mineral should contain iron or a reduced form of sulfur.

Biomining processes use the action of microbes for one of two purposes (Rawlings, 2005). Either to convert insoluble metal sulfides (or oxides) to water soluble metal sulfates or as a pretreatment process to open up the structure of the mineral thereby permitting other chemicals to better penetrate the mineral and solubilize the desired metal. An example of the first type of process is the conversion of insoluble copper present in minerals such as covellite (CuS) or chalcocite (Cu_2S) to soluble copper sulfate. An example of the second is the removal of iron, arsenic, and sulfur from gold-bearing arsenopyrite so that the gold that remains in the mineral is more easily extracted by subsequent treatment with cyanide. Both are oxidation processes, but when the metal to be recovered is extracted into solution, the process is known as bioleaching, whereas when the metal remains in the mineral, bioleaching is an inappropriate term and the process should strictly be referred to as biooxidation. The term bioleaching is frequently used for both.

Mechanisms of biologically assisted leaching

Current understanding is that biooxidation is primarily a chemical process. Sand and coworkers have proposed that minerals can be divided into two broad categories, acid-insoluble minerals that are solubilized through oxidation by ferric iron (e.g., FeS_2 , MoS_2 , and WS_2) and acid-soluble minerals that are oxidized by the combined action of ferric iron and protons (e.g., ZnS , PbS , FeAsS , CuFeS_2 ,

and MnS_2). The role of the microorganisms is to provide the ferric iron and sulfuric acid leaching agents. Leaching reactions have been presented in Schippers and Sand (1999) and Rohwerder et al. (2003) and are reviewed in Rawlings (2005).

Because bioleaching processes are chemistry-driven, if a mineral (such as chalcopyrite) is recalcitrant to biooxidation at 40°C , the solution to the problem lies primarily in the realm of chemistry rather than biology. For example, an increase in the temperature of the biooxidation process to 80°C will allow the chemical reactions to take place at a much faster rate. However, the biology needs to follow the chemistry, and microorganisms that are capable of iron and sulfur oxidation at 80°C are required to generate or regenerate the lixiviants (leaching chemicals).

Although it is possible to separate the chemistry of metal solubilization from the biology into two different processes, separation is unlikely to be as efficient as when both processes are carried out together. The reason for this is that the role of the microorganisms is considered to be more than the generation of the ferric iron and acid required for the chemistry of mineral biooxidation. Contact between the microbes and the mineral is important (though not essential) because the microorganisms produce an exopolysaccharide layer when attached to a mineral (Sand et al., 1995). This layer serves as a reaction space where mineral dissolution reactions take place more efficiently than in the bulk solution. Increased efficiency is partly because conditions within the exopolysaccharide layer (e.g., concentration of ferric iron, redox potential, and pH) are substantially different and more favorable for leaching compared with conditions in the bulk solution (Rawlings, 2005).

Biomining processes

Heap reactors

Commercial mineral bioleaching can take place using a low technology process such the irrigation of waste ore dumps (Brierley, 1982). The efficiency of metal recovery may be improved by the construction and irrigation of specially designed heaps rather than by the irrigation of an existing, nonengineered dump (Brierley, 1982; Rawlings et al., 2003). During heap construction, agglomerated ore is piled onto an impermeable base and supplied with an efficient leach liquor distribution and collection system. Acidic leaching solution is percolated through the crushed ore, and microbes growing on the surface of the mineral in the heap produce the ferric iron and acid that carry out mineral dissolution and metal solubilization. Good aeration enhances the metal leaching reaction. Aeration can be passive, with air being drawn into the reactor as a result of the flow of liquid or may be active with air blown into the heap through piping installed near the bottom. Metal-containing leach solutions that drain from the heap are collected and sent for metal recovery. Heap reactors can be of enormous size (Rawlings et al., 2003), are

relatively cheap to construct and operate, and are therefore suited to the treatment of lower grade ores. Compared with tank reactors, the metal recovery efficiency of heap reactors tends to be low. Heap reactors are more difficult to aerate efficiently and undesirable gradients of pH, nutrients, and liquor channeling are difficult to manage. In addition, although initial rates of bioleaching can be improved by effective heap inoculation, it is difficult to achieve in practice and nondeliberate inoculation that occurs during irrigation may be the main method by which microorganisms are spread through a heap.

Tank reactors

Continuous-flow stirred tank reactors placed in series are used to treat high-value finely milled mineral concentrate or ore. Such tanks can be of considerable size, for example, the 1,300 m³ tanks used to process cobalt-containing pyrite at Kasese, Uganda. Mineral concentrate is added to the first tank, together with inexpensive inorganic nutrients in the form of ammonia- and phosphate-containing fertilizers. The mineral suspension flows through the series of highly aerated tanks that are pH- (typically pH 1.5–1.6) and temperature-controlled. Stirred tank reactors that operate at 40°C and 50°C have proven to be highly robust, and very little process adaptation is required for the treatment of different mineral types. Mineral solubilization takes place in days rather than the weeks or months required in heap reactors. A constraint on the operation of stirred tank reactors is the quantity of solids (pulp density) that can be maintained in suspension, which is limited to about 20%. At pulp densities >20%, physical mixing and microbial problems occur. The liquid becomes too thick for efficient gas transfer and the shear force induced by the impellers cause physical damage to the microbial cells. The limitation in solids concentration together with higher capital and running costs has restricted the use of stirred reactors to high value minerals or mineral concentrates. Stirred tanks are used as a pretreatment process for gold-containing arsenopyrite concentrates, with the first of these having been built at the Fairview mine, Barberton, South Africa in 1986. The largest stirred tank process is at Sansu in the Ashanti goldfields of Ghana, West Africa, where 960 tonnes of gold concentrate are processed per day.

Types of microorganisms

Both heap and tank biooxidation processes contain a variety of microorganisms, with two different organisms usually dominating: an iron-oxidizer and a sulfur-oxidizer. A wide variety of these microorganisms may be present (Rawlings and Johnson, 2007). Irrespective of the type of process or temperature, these microbes have several features in common that make them suitable for their role in mineral dissolution. They grow autotrophically by fixing CO₂ from the atmosphere which makes it unnecessary to provide them with a fixed carbon source. Their energy is obtained by using either ferrous iron or reduced

inorganic sulfur compounds (some use both) as electron donors. Oxygen is generally used as the electron acceptor. All are acidophiles and grow in low-pH environments (pH 1.4–1.6 is typical) and they tend to be tolerant of a wide range of metal ions (Dopson et al., 2003). These very modest nutritional requirements can generally be met by the aeration of the iron- and/or sulfur-containing mineral suspension in water or the irrigation of a heap. Small quantities of inorganic fertilizer may be added to ensure that nitrogen, phosphate, potassium, and trace element limitation does not occur.

The types of organisms found in heap and tank reactors that operate at different temperatures have been reviewed (Rawlings and Johnson, 2007). In general, bacteria belonging to the genera *Acidithiobacillus* and *Leptospirillum* tend to dominate the processes up to 40°C, with those belonging to the genera *Acidithiobacillus*, *Leptospirillum* and *Sulfobacillus* dominating the processes between 45 and 55°C. In high-temperature processes (60–80°C), archaea such as *Acidianus*, *Metalsphaera*, and *Sulfolobus* are responsible for iron- and sulfur-oxidation rather than bacteria.

Definition

Active or passive microbially induced or mediated consolidation, cleaning, and/or protection of (stone) artworks affected by chemical, physical, and/or biological weathering phenomena. Bioprotection includes the microbially mediated removal (cleaning) of deleterious compounds (sulfates, nitrates, and/or organics), and the in situ cementation (consolidation) of ornamental materials via microbially induced biomineralization. Bioprotection also occurs naturally on rock surfaces where microorganisms aid in the formation of cementing phases such as oxalates and carbonates, and biofilms.

Introduction

The term bioprotection has been applied to a range of processes and applications involving microorganisms. They include microbe-induced defense response in plant–soil interactions, plant/crop treatment, food processing, and toxic metal decontamination (Glazer and Nikaido, 2007), prevention of wood decay (Dawson-Andoh and Morrell, 1992), inhibition of steel corrosion (Volkland et al., 2000), natural protection of rock outcrops (Carter and Viles, 2005) and building stones (Di Bonaventura et al., 1999), as well as cultural heritage conservation (Ciferri et al., 2000; Rodriguez-Navarro et al., 2003; Ramirez et al., 2005; Webster and May, 2006). Here, the term bioprotection refers both to the use of microorganisms (mainly bacteria) for the conservation of stone artworks, and to the microbially mediated formation of natural protection layers on rock outcrops and stone surfaces. Such meanings are the most commonly used and accepted in

geobiology, as they involve the interaction between the biosphere and the geosphere.

Although “carved in stone” is meant to be durable or eternal, ornamental stones are subjected to a range of physical, chemical, and biological weathering phenomena that lead to their eventual crumbling and disintegration. Such weathering processes have been exacerbated by anthropogenic emission of pollutants since the Industrial Revolution (Winkler, 1994). As a consequence, stone monuments and statuary are at risk worldwide.

Granites, sandstones, and carbonate rocks – limestone, dolostone, and marble – are among the most common stones used in monuments and statuary. Carbonate stones, made up of calcite (CaCO_3) and/or dolomite ($\text{CaMg}(\text{CO}_3)_2$), are particularly prone to chemical weathering in polluted (urban) environments, as exemplified by the decay of the Parthenon or the Taj Mahal. Wet (acid rain) and dry deposition of atmospheric pollutants contribute to the leaching of these sparingly soluble carbonates and the formation of sulfate – gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) – crusts, also named “black crusts” (Figure 1). Carbonate stones are also prone to physical–mechanical weathering associated to salt crystallization, insolation weathering, frost damage, and hydric expansion/contraction (Winkler, 1994; Gauri and Bandyopadhyay, 1999; Rodriguez-Navarro et al., 2003). Biodeterioration is also a major

Bioprotection, Figure 1 Black crusts developed on a limestone gargoyle at the Royal Chapel, Granada (Spain).

Such meanings are the most commonly used and accepted in

geobiology, as they involve the interaction between the biosphere and the geosphere.

Although “carved in stone” is meant to be durable or eternal, ornamental stones are subjected to a range of physical, chemical, and biological weathering phenomena that lead to their eventual crumbling and disintegration. Such weathering processes have been exacerbated by anthropogenic emission of pollutants since the Industrial Revolution (Winkler, 1994). As a consequence, stone monuments and statuary are at risk worldwide.

Granites, sandstones, and carbonate rocks – limestone, dolostone, and marble – are among the most common stones used in monuments and statuary. Carbonate stones, made up of calcite (CaCO_3) and/or dolomite ($\text{CaMg}(\text{CO}_3)_2$), are particularly prone to chemical weathering in polluted (urban) environments, as exemplified by the decay of the Parthenon or the Taj Mahal. Wet (acid rain) and dry deposition of atmospheric pollutants contribute to the leaching of these sparingly soluble carbonates and the formation of sulfate – gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) – crusts, also named “black crusts” (Figure 1). Carbonate stones are also prone to physical–mechanical weathering associated to salt crystallization, insolation weathering, frost damage, and hydric expansion/contraction (Winkler, 1994; Gauri and Bandyopadhyay, 1999; Rodriguez-Navarro et al., 2003). Biodeterioration is also a major

Bioprotection, Figure 1 Black crusts developed on a limestone gargoyle at the Royal Chapel, Granada (Spain).

contributor to the decay of stones in general, and carbonate stones in particular (McNamara and Mitchell, 2005).

Conservation of decayed stoneworks typically involves cleaning (by mechanical or chemical means) and/or protection/consolidation. Organic (e.g., acrylic or epoxy resins), organo-inorganic (e.g., ethyl silicates), and inorganic (e.g., $\text{Ba}(\text{OH})_2$ and $\text{Ca}(\text{OH})_2$ solutions) protection/consolidation treatments have been applied in the past to alter or mitigate stone decay (Lazzarini and Tabasso, 1986; Price, 1996). However, none of these treatments have been proven to be satisfactory (see Rodriguez-Navarro et al., 2003 and references therein). The limitations and drawbacks of these “classic” conservation treatments have prompted the search for new methods to clean, protect and consolidate weathered ornamental stones. One promising line of research has focused on microbial bioprotection as a new means for the restoration and consolidation of ornamental stone.

Microbial-stone interactions: biodeterioration versus bioprotection

It has been known for decades that microbes actively contribute to the degradation of ornamental stone (McNamara and Mitchell, 2005). For instance, the metabolic activity of nitrifying bacteria (*Nitrosomonas* sp. and *Nitrobacter* sp.) results in the production of nitric acid, which in turn causes dissolution of stone and formation of deleterious nitrate salts (Fernandez, 2006). Sulfur-oxidizing bacteria such as *Thiobacillus* sp. produce sulfuric acid and contribute to the development of sulfate crusts (Warscheid and Braams, 2000). Biofilms can exacerbate microbial biodeterioration as they provide a shelter for the aforementioned bacteria, and act as a reservoir for nutrient storage (McNamara and Mitchell, 2005). Wetting and drying of the biofilm matrix may lead to swelling/shrinking of the extracellular polymeric substances (EPS), causing mechanical damage to the host stone (Warscheid and Braams, 2000).

Although microbes are often the problem, they can also be the solution (Rinaldi, 2006). For instance, the anaerobic sulfate-reducing bacteria *Desulfovibrio desulfuricans* and *D. vulgaris* have been shown to be effective for the removal of gypsum crusts (Webster and May, 2006; Cappitelli et al., 2007). Similarly, nitrate salts can be eliminated through the application of nitrate-reducing bacterial cultures (Fernandez, 2006), while *Pseudomonas stutzeri* has been successfully applied to eliminate organic residues from frescoes (Ranalli et al., 2005).

There is growing evidence that several microorganisms contribute to the natural bioprotection of rock outcrops (Carter and Viles, 2005) as well as ornamental stone (Di Bonaventura et al., 1999) via the formation of biofilms and cemented surface layers. Some bacterial communities can promote the production of protective calcium oxalates on building stone (Di Bonaventura et al., 1999), or inhibit calcite dissolution (Rinaldi, 2006). Numerous strains of

bacteria isolated on different building stones are able to induce the precipitation of calcium carbonate (Urzi et al., 1999), an effect that may have aided in the natural protection of weathered ornamental stones. This latter ability has opened new ways for the effective protection and consolidation of decayed ornamental stones based on the in situ mineralization of bacterial carbonate cement (Rodriguez-Navarro et al., 2003; Webster and May, 2006; Jimenez-Lopez et al., 2007).

Bacterially mediated biomineralization of carbonates

The precipitation of carbonate minerals mediated or induced by both autotrophic and heterotrophic bacteria have attracted a substantial amount of research (see recent review by Wright and Oren, 2005). Bacterial precipitation of calcium carbonate has important implications in the past and present formation of carbonate rocks and sediments (Rodriguez-Navarro et al., 2003; Wright and Oren, 2005). It is known that cyanobacteria have aided in the formation of mineralized stromatolites since the Precambrian age (Konhauser, 2007), their photosynthetic activity thus contributing to atmosphere oxygen increase and CO_2 budgeting by carbonate precipitation. While early work (until the 1980s) examined the ability of photosynthetic bacteria to precipitate calcium carbonates in marine environments, precipitation of carbonates induced by heterotrophic bacteria in other environments such as caves, soils, and monuments has become the subject of much research in recent decades (Boquet et al., 1973; Urzi et al., 1999).

Bacteria play both passive and active roles in carbonate nucleation (Mitchell and Ferris, 2006). In the first case, the metabolic activity of heterotrophic bacteria (e.g., ammonification of amino acids, urea degradation, and dissimilatory reduction of nitrates and sulfates), or photosynthetic HCO_3^- consumption and OH^- production by cyanobacteria, increases the alkalinity (high pH, and elevated CO_3^{2-}) in the microenvironment surrounding the bacterial cells. This in turn increases supersaturation with respect to calcium carbonate if free Ca^{2+} is present, thus favoring calcification. Bacterial cell walls and/or sheets, as well as EPS, can actively aid in carbonate crystallization by providing heterogeneous nucleation sites (Ercole et al., 2007; Rodriguez-Navarro et al., 2007).

Bioprotection of stone by bacterial biomineralization of carbonates

Based on previous work on the natural ability of many heterotrophic bacteria to induce calcium carbonate precipitation, Adolphe et al. (1990) patented a method, CALCITE, for bacterial bioprotection of ornamental stones. The authors showed that calcinogenic bacteria, such as those typically found in soils (Boquet et al., 1973), were able to precipitate calcite on the surface of weathered limestone, thus contributing to their protection and consolidation. Le Métayer-Levrel et al. (1999) reported the

“successful” application of such a method on a sixteenth century limestone castle. Nonetheless, the authors used *Bacillus cereus* cultures, which may pose a health risk. In addition, potentially harmful biofilm formation and only a few micrometers thick consolidated layer were observed. Tiano et al. (1999) evaluated the effectiveness of such a treatment for bioprotection of a highly porous limestone (Pietra de Lecce) using *Micrococcus* sp. and *B. subtilis*. They observed detrimental obstruction of pores (presumably by biofilm formation), and called attention to other potential drawbacks e.g., reaction of the stone and by-products of bacterial activity, and the formation of stain patches. Rodriguez-Navarro et al. (2003) showed that such limitations could be overcome by using different culture media and a non-pathogenic carbonate-producing heterotrophic soil bacteria, *Myxococcus xanthus*. The treatment resulted in deep consolidation of a porous limestone (calcarenite) with new bacterial calcium carbonate cement, without detrimental pore plugging or extensive biofilm formation. *M. xanthus* metabolic activity results in the release of NH_3 , which leads to a pH rise in the medium surrounding the bacterial cells. This in turn favors carbonate supersaturation and results in CaCO_3 precipitation on different calcareous stones such as limestone and marble (Figure 2). Carbonates typically form on the bacterial cell walls, where heterogeneous nucleation is facilitated, and grow as a coherent cement (often epitaxially) on the stone support. Rodriguez-Navarro et al. (2003) also showed that the new bacterial calcite cement was tougher and more resistant to dissolution than the original calcite

in the stone. They interpreted these results considering that organic by-products of bacterial activity were incorporated into the bacterial calcite, which was in fact a (bio) composite material. Interestingly, Ben Chekroun et al. (2004) and Rodriguez-Navarro et al. (2007) showed that *M. xanthus* induced the precipitation of either calcite or vaterite just by modifying the culture medium. These results demonstrate that polymorph selection in carbonate precipitation is not strain specific. On the other hand, recent research using *B. subtilis* (Perito and Mastromei, 2003), *B. sphaericus* and *B. lentus* (Dick et al., 2006) shows that the range of microorganisms that can contribute to the bioprotection of ornamental stone via the precipitation of carbonates is very wide. In addition, it has been shown that bacteria such as *M. xanthus* can precipitate a range of minerals, other than carbonates, just by changing the composition of the culture medium (Ben Chekroun et al., 2004). These results imply that an accurate selection of growth media and bacterial strains could yield improved protection and consolidation of ornamental stones with disparate composition and textures.

Bioprotection treatments based on bacterial biomineralization are not restricted to ornamental stone. Castanier et al. (1996) used *Pseudomonas* sp. for calcite precipitation as a cementing phase in a biological mortar. Bang et al. (2001) have reported that polyurethane-immobilized *B. pasteurii* (a carbonatogenic ureolytic bacteria) can fill the cracks in concrete. Whiffin et al. (2007) have shown that carbonate precipitation induced by *Sporosarcina pasteurii* contributes to soil strengthening.

Summary

Weathered ornamental stones typically contain a variety of endolithic and epilithic microbial communities (Urzi et al., 1999; McNamara and Mitchell, 2005). Application of bacterial treatments that include a nutritive medium may thus activate, among the microbial community contained in the stones, those bacteria that are able to induce the precipitation of calcium carbonate. In this respect, Jimenez-Lopez et al. (2007) have shown that the application of sterile nutritive media to porous limestone is able to activate carbonatogenic bacteria. As a consequence of the growth of these bacteria, an alkalization occurs that results in calcium carbonate precipitation. The new precipitate is compatible with the substrate and consolidates the stone without pore plugging. Such effects are reinforced by the presence of *M. xanthus*. Therefore, a good candidate to in situ consolidate decayed porous limestone is the application of a sterile culture medium with specific characteristics that favor the development of calcinogenic bacteria, while limiting the proliferation of detrimental microbiota (Jimenez-Lopez et al., 2007). Such an alternative to the direct application of life cells is highly promising. Finally, bacterial biomineralization of silicates as a means to consolidate non-carbonate stones such as granite and sandstone is another topic that should be further studied.

BIOSIGNATURES IN ROCKS

Frances Westall, Barbara Cavalazzi
 Université de Orléans, Orléans, France

Definition

Biosignatures are morphological, chemical (organic, elemental and/or mineral), and isotopic traces of organisms preserved in minerals, sediments, and rocks. They represent the physical presence of the organisms as well as evidence of their metabolic activities and metabolites.

The nature of biosignatures

In this entry, we review (1) the nature of biosignatures in rocks, (2) how they are produced, and (3) the relevance of biosignatures and their astrobiological implications. Examples of biosignatures from throughout the rock record are given. We will limit our discussion to microbial biosignatures.

Microorganisms are characterized by (1) structural components, such as cells, colonies, biofilms/mats, extracellular polymeric substances (EPS); (2) the chemical composition of the different structural elements, including organic molecules and other essential elements; and (3) their living processes, including metabolic activity leading to the fractionation of elements such as C, S, O, N, P, and Fe, as well as cell division. Indirectly, microorganisms are also characterized by (4) the effects of their

physical presence and metabolic products on their immediate environment. These effects may be preserved on a microscopic to macroscopic scale. They include the precipitation of minerals; element leaching from, and dissolution of, minerals and rocks (biocorrosion); influence on mineral grain size and habit; the formation of microbially induced sedimentary structures (MISS; cf. Noffke et al., 2003) and biostabilization of sedimentary surfaces; and the formation of microbialites (e.g., microbial mounds, stromatolites, thrombolites) and microbial fabrics (e.g., clots, peloids, fenestralae). All of these phenomena can leave morphological, chemical, or isotopic traces in rocks (Table 1), but do not always do so. The ultimate fate of biosignatures is dependent upon their immediate preservation and the history of the sediments and rocks during subsequent diagenesis, metamorphism, and weathering.

The various types of biosignatures are discussed in detail elsewhere in this volume. Our aim here is to provide a brief overview of the broad range of biosignatures in rocks and to discuss their relevance and astrobiological implications.

Biosignatures of cell components and metabolic activity

Fossil carbon molecules

All terrestrial life consists of assemblages of macromolecules based on carbon (with water as the universal solvent, Brack, 2002) and the different components of the cell, i.e., cytoplasm, chromosomes, chloroplast, and cell walls and envelopes, etc., are characterized by molecules of different composition and structure. Molecular degradation starts with the death of the organism and may also be aided by the activity of other microorganisms, e.g., the heterotrophs, who obtain their energy and carbon from the breakdown of organic substances. The chemical changes that take place during degradation (diagenesis) are dependent on the redox state and water chemistry of the environment. Degradation of macromolecules to form “fossil” molecules results in the gradual loss of the functional groups. Specific characteristics of fossil molecules that suggest a biological origin include (1) enantiomeric excess (chirality), (2) diastereoisomeric preference, (3) structural isomer preference, (4) repeating constitutional subunits or atomic ratios, (5) systematic isotopic ordering at molecular and intramolecular levels, and (6) uneven distribution patterns or clusters, such as C-number, concentration, or $\delta^{13}\text{C}$, of structurally related compounds (Summons et al., 2008).

Preservation of fossil molecules

Fossil organic molecules or biomarkers are best preserved in anaerobic environments where they are protected from abiotic oxidation or aerobic microbial degradation. Subsequent burial, metamorphism, and heat events (e.g., hydrothermal/volcanic activity) affect the “maturity” or degradation state of the organic matter. This results in the formation of different types of kerogen characterized

by H/C ratios ranging from >1.25 for Type I kerogen to <0.5 for type IV kerogen. The small molecular size of some of the degraded molecules means that they are readily mobile and can be transported into other formations with which they are not syngenetic, thus causing contamination. The oldest known biomarkers occur in carbonaceous oil shales from the 2.7 Ga-old Fortescue Group in Australia where molecules such as hopanes and steranes, the degradation products of prokaryotes (specifically aerobic photosynthesizers, cyanobacteria) and eukaryotes, respectively, were interpreted as evidence for oxygenic photosynthetic activity by 2.7 Ga (Brocks et al., 1999) and, more importantly, the early rise of eukaryotes (Summons et al., 1999). These biomarkers have, however, recently given rise to controversy regarding their syngeneticity (Eigenbrode and Freeman, 2006; Rasmussen et al., 2008).

Syngenetic organic molecules occur in even older sediments but the kerogens in the volcanic sediments in the 3.5–3.3 Ga-old Barberton (South Africa) and Pilbara (Australia) greenstone belts are so degraded by age and low-grade metamorphism (prehnite–pumpellyite to lowest greenschist facies) that they no longer contain recognizable compositional biomarkers. The kerogens do, however, retain structural characteristics that are indicative of a biological origin (Westall et al., 2006a; Derenne et al., 2008). Evidence of syngeneticity of the kerogens analyzed is provided by in situ Raman spectra showing D and G peaks indicative of a maturity consistent with the metamorphic grade of the rocks (Westall et al., 2006a), as well as covalent linking of the molecular structures in the kerogen matrix (Derenne et al., 2008).

Traces of cell metabolism and metabolites

The metabolic activity of microorganisms can result in elemental, isotopic, and mineral signatures that can be preserved in rocks.

Bioelements: Unusual concentrations of metals may be associated with microorganisms and their metabolic products. Adsorption of these elements may be either an active or a passive process. Active adsorption includes the chelation of metals to anionic functional groups in the cell walls to neutralize their negative charges, thus contributing to the stability of the cell wall. Microorganisms also require metals, such as Fe, Co, Ni, Cu, Mn, Mo, Se, and V, for certain enzymatic activities (Banfield et al., 2001). They are actively adsorbed onto the cell walls by ligands that are specific for a particular metal (Konhauser, 2007). Microorganisms can also concentrate toxic elements, such as U, Cu, Pb, Al, As, and Cd, as well as precious metals (U, Cu, Pd, Pt, and Au) that are bound to cells and S-layers (Pollmann et al., 2006).

Passive adsorption of metal ions to cell surfaces is an additional kind of metal sequestration (Ledin, 1999). The availability of functional molecules, such as carboxyl or phosphate groups, determines the amount of metals that can be sorbed to the cell surface. With their large quantities of peptidoglycan, Gram positive bacteria can readily scavenge metal ions. Gram negative bacteria, on the other hand, are characterized by only a thin layer of peptidoglycan sandwiched between an outer lipopolysaccharide layer and an inner phospholipid layer. The amount of metal that they can bind is an order of magnitude less than that of the Gram positive bacteria (e.g., Beveridge et al., 1982). Microbial EPS is also an important factor in the binding of metals owing to their highly hydrated character that allows the metal ions to freely migrate through the structure (Geesey and Jang, 1989). This characteristic means that microorganisms, such as encapsulated bacteria, are more likely to chelate metals than non-encapsulated varieties. Metal-replaced microorganisms are common and are among the oldest traces of life. Fossil microorganisms preserved as pyritized filaments occur in a 3.2 Ga-old volcanogenic

massive sulfide deposit (the equivalent of a fossilized black smoker) from the Pilbara in Australia (Rasmussen, 2000). A younger example consists of ZnS-replaced filaments in Triassic calcareous rocks in the southern Alps (Kucha et al., 2005).

Concentrations of other biologically important elements, such as P and S, are considered to be significant biosignatures. For example, the combination of graphite associated with apatite inclusions (apatite can be a biomineral, cf. Table 2) and a $\delta^{13}\text{C}$ of -26‰ in a highly metamorphosed rock from the 3.85 Ga-old Akilia province in W. Greenland was interpreted as a biosignature by Mojzsis et al. (1996). However, van Zuilen et al. (2002) demonstrated that abiological processes linked to alteration of the rocks by hydrothermal circulation could have produced carbon via the Fischer–Tropsch process with a similar isotopic signature. On the other hand, phosphatized microorganisms are well-known from the rock record. The spectacular preservation of soft body parts of animals, birds, amphibians, and fish from the Eocene Messel oil shales in Germany is due to phosphatized microbial biofilms that coated the dead organisms (Liebig et al., 1996).

High concentrations of sulfur can be found in kerogen owing to the process of sulfurization during which sulfur, liberated from degrading organic matter by the activity of sulfur-reducing bacteria, is bound to the organic macromolecules. Thus, the identification of the S-molecule thiophene in the organic cell walls of microfossils from the

800 My-old Draken Formation of Svalbard (Lemelle et al., 2008) and even in 2.7 Ga-old kerogen associated with stromatolites from the Tumbiana Formation in the Pilbara (Lepot et al., 2008) has been linked to the degradation of organic matter by sulfur-reducing bacteria.

Biominerals: Minerals of different phases can be formed both actively and passively by microorganisms in biologically controlled and biologically induced processes, respectively. Microbially induced mineralization occurs either as a result of changes in the environment of a microorganism caused by the excretion of metabolic waste products, enzymatic mediated changes in the redox state, or simply the presence of a charged cell surface that attracts mineral nucleation (Banfield et al., 2001; Konhauser, 2007). We have seen above that reactive functional group sites on microbial surfaces readily chelate metal ions. In the same way mineral nuclei in saturated solutions bind to the surfaces of cells and their extrapolymeric substances (EPS), often completely entombing the microorganisms. A non-exhaustive list of microbially induced mineral precipitates is given in Table 2.

Iron hydroxides (ferrihydrite) are among the most common microbially induced deposits and may be formed passively, or by the activities of chemoheterotrophic, photoautotrophic, or chemolithoautotrophic (e.g., *Gallionella*) microorganisms. The ferric hydroxides may act as precursors for Fe oxides, such as hematite. Manganese nodules are an example of microbially induced

Biosignatures in Rocks, Table 2 Non-exhaustive list of microbially induced mineral precipitates

Metal oxides	Fe/Mn hydroxides and oxyde-hydroxides (or oxyhydroxides), e.g., ferrihydrite (ferric hydroxide), $\text{Fe}^{3+}_2\text{O}_3 \cdot 0.5(\text{H}_2\text{O})$, goethite, $\text{Fe}^{3+}\text{O}(\text{OH})$, schwertmannite, $\text{Fe}^{3+}_{16}\text{O}_{16}(\text{OH})_{12}(\text{SO}_4)_2$
Amorphous silica	Fe/Mn/Ti oxides, e.g., magnetite, $\text{Fe}^{3+}_2\text{Fe}^{2+}\text{O}_4$, hematite, $\text{Fe}^{3+}_2\text{O}_3$, anatase, TiO_2
Carbonates	Opal, $\text{SiO}_2 \cdot n(\text{H}_2\text{O})$, e.g., opal-A and opal-A/CT
Carbonates	Ca-carbonates, e.g., calcite, $\text{Ca}(\text{CO}_3)$, magnesian calcite, High-/Low-Mg $\text{Ca}(\text{CO}_3)$, aragonite, CaCO_3 , dolomite, $\text{CaMg}(\text{CO}_3)_2$
Carbonates	Magnesite, $\text{Mg}(\text{CO}_3)$
Carbonates	Strontianite, $\text{Sr}(\text{CO}_3)$
Phosphates	Ca-phosphates, e.g., apatite, $\text{Ca}_5(\text{PO}_4)_3(\text{OH}, \text{F}, \text{Cl})$, carbonate-hydroxylapatite, $\text{Ca}_5(\text{PO}_4)_3(\text{OH})$, francolite, or carbonate fluoroapatite, $\text{Ca}_5(\text{PO}_4)_3\text{F}$
Phosphates	Fe-phosphates, e.g., vivianite, $\text{Fe}^{3+}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$
Sulfates	Barite, BaSO_4
Sulfates	Celestine, SrSO_4
Sulfates	Gypsum, $\text{Ca}(\text{SO}_4) \cdot 2(\text{H}_2\text{O})$
Sulfates	Fe-sulfates, e.g., jarosite, $\text{KFe}^{3+}_3(\text{SO}_4)_2(\text{OH})_6$
Sulfides	Chalcopyrite, $\text{CuFe}^{2+}\text{S}_2$
Sulfides	Galena, PbS
Sulfides	Greigite, Fe_3S_4
Sulfides	Mackinawite, FeS
Sulfides	Millerite, NiS
Sulfides	Pearceite, $\text{Ag}_{16}\text{As}_2\text{S}_{11}$
Sulfides	Proustite, Ag_3AsS_3
Sulfides	Pyrite, Fe^{2+}S_2
Sulfides	Sphalerite, $(\text{Zn}, \text{Fe})\text{S}$
Silicates	Clay minerals, e.g., phillipsite, $(\text{Ca}, \text{Na}, \text{K})1-2(\text{Si}, \text{Al})_8\text{O}_{16} \cdot 6(\text{H}_2\text{O})$, chamosite, $(\text{Fe}^{2+}, \text{Mg}, \text{Fe}^{3+})_5\text{Al}(\text{Si}_3\text{Al})\text{O}_{10}(\text{OH}, \text{O})_8$, illite, $(\text{K}, \text{H}_3\text{O})(\text{Al}, \text{Mg}, \text{Fe})_2(\text{Si}, \text{Al})_4\text{O}_{10}[(\text{OH})_2, (\text{H}_2\text{O})]$, smectite $(\text{Na}, \text{Ca})\text{Al}_4(\text{Si}, \text{Al})_8\text{O}_{20}(\text{OH})_4 \cdot 2(\text{H}_2\text{O})$

iron-manganese oxides that can form volumetrically important deposits in the deep-sea and lacustrine environments (Mero, 1962).

Amorphous silica commonly nucleates passively onto the surfaces of microorganisms in hot spring environments (Figure 1a) (e.g., Cady and Farmer, 1996) and precipitates from saturated solutions in other environments as well. For example, Monty et al. (1991) and Westall (1994) documented silicified microorganisms in the pore space of 15–10 My-old deep-sea sediments. At the other end of the geological record, silica-saturated seawaters on the early Earth led to the silicification of early Archaean microbes and the preservation of the oldest known traces of life (Figure 1b) (Walsh, 1992; Westall et al., 2001, 2006a, b; Westall and Southam, 2006).

Perhaps the most geologically significant microbially induced mineral deposits are those related to carbonates. The carbonate minerals are produced by processes including mineralization of microbial surfaces, chemical precipitation from supersaturated solutions, and physical erosion of preexisting carbonates (Riding, 2000). Microbial carbonates occur in a wide variety of environments ranging from deep-water cold seeps (Figure 2) (e.g., Cavalazzi et al., 2007), shallow-water platforms (Figure 3a) (e.g., Monty, 1995), lacustrine environments (Figure 3b and c) (e.g., Laval et al., 2000) to carbonate (travertine) springs (e.g., Chafetz and Folk, 1984).

Biologically controlled mineralization occurs when microorganisms exert direct control on the nucleation and growth of the mineral (Mann, 1988). The resulting minerals are characterized by their highly ordered crystal-line structure, size, and morphology. Chains of single-domain magnetite crystals are formed in this way by magnetotactic bacteria (e.g., Bazylinski et al., 1995) and Chang and Kirschvink (1989) record chains of magnetite crystals in the 1.9 Ga-old Gunflint Formation (Canada) that are similar in size and shape to those produced by

recent bacteria. Indeed, the presence of chemically pure magnetite crystals with a specific size/shape range in an ancient Martian meteorite, ALH84001, is one of the key lines of evidence for life on Mars by 3.9 Ga (McKay et al., 1996; Thomas-Keprta et al., 2001, 2002; Friedmann et al., 2001). However, the supposedly biogenic magnetites form only a fraction (<30%) of a larger population that includes magnetites of clearly abiological origin and it is questioned whether this assemblage is purely fortuitous. Moreover, similar magnetites have been produced in the laboratory by abiogenic processes (Golden et al., 2004).

The presence of microbial metabolites plus the physical presence of the organic components can have an enormous effect on the elemental composition and dissolution of minerals, as well as the shape and size of the crystals. Microbial dissolution of nonorganic substrates is a common process, especially in oligotrophic environments where access to essential elements is necessary for survival. Microbial dissolution of silicate minerals, such as feldspars and mafic minerals, contributes strongly to crustal weathering. Microbial colonies and biofilms attach to a mineral surface and obtain their nutrients by physical disaggregation of the minerals, as well as by dissolution through the production of organic acids (Konhauser et al., 1994; Konhauser, 2007). Etching patterns produced in the presence of actively metabolizing cells show clear differences to those produced by inorganic acids (Figure 4) (Welch et al., 2002). Microbial etching of volcanic glass (e.g., Thorseth et al., 1995) has recently received much attention because certain tunnel-like structures in ~3.5 Ga-old pillow lava rims from the Barberton and Pilbara greenstone belts have been interpreted as microbial corrosion biosignatures (Furnes et al., 2004; Banerjee et al., 2006).

Compositional variability can occur in minerals and rocks as a result of microbial metabolic activity. The distribution of elements (major, minor, and trace) in the

surfaces of minerals colonized by microorganisms may be different to that of the bulk mineral because the microorganisms leach out those elements that are important for their metabolic activities. For instance, sulfur can be leached from sulfides by sulfur-oxidizing bacteria (McGuire et al., 2001) and phosphorus from P-containing minerals is leached in P-poor environments (Taunton et al., 2000a, b). Also, unusual concentrations of trace elements may be associated with mineral-entombed microorganisms since the microbes preferentially concentrate elements that are necessary for their metabolic functions, such as Co, Ni, Cu, Mn, Mo, Se, and V, (Banfield et al., 2001).

The incorporation of organic compounds within a mineral structure may be indicative of biologically induced precipitation as, for instance, when microorganisms are permeated and entombed by minerals (Westall et al., 1995, 2000). Indeed, association of organic molecules with microfossils is a key complementary biosignature for traces of early life on Earth (Westall and Southam, 2006).

Whereas biologically controlled mineral growth produces specific crystalline shapes, biologically induced mineralization produces minerals with non-perfect habits (Banfield et al., 2001) due to alteration of the stability of the crystal surface in the presence of organics (Mann et al., 1993; Albeck et al., 1996). However, the presence of organic matter does not always have an influence on the morphology of a mineral precipitate. For instance, Orange et al. (2009) note that silica precipitated in nutrient media with and without cells had exactly the same structure, the only difference being the visible incorporation of EPS in the medium with cells.

A number of studies have noted a distinct difference in the size of minerals precipitated in the presence of microorganisms and those precipitated abiologically with the former being smaller than the latter. Douglas et al. (2008), for example, document smaller biofilm-induced calcite and Mn-oxyhydroxide mineral precipitates compared to abiogenic gypsum precipitates in an unusual microbial mat from a Death Valley pool.

Isotopic fractionation: Until recently, the preference of microorganisms for the lighter stable isotope of carbon ^{12}C over the heavier one, ^{13}C was considered to be one of the most important biosignatures in rocks. Indeed, Schidlowski (1988) had shown that these signatures can be traced back to rocks 3.8 Ga-old from the Isua province in Greenland. Recent studies, however, have demonstrated that $^{12}\text{C}/^{13}\text{C}$ ratios similar to those produced by living organisms occur in carbon produced by abiotic hydrothermal/metasomatic Fischer–Tropsch synthesis (e.g., van Zuilen et al., 2002). Contamination of the rock by younger organisms can also produce an erroneous biosignature. Westall and Folk (2003), for instance, identified Holocene fossilized endolithic microorganisms in the Isua banded iron formation that was used for Schidlowski's (1988) isotopic studies.

Biosignatures of structural components

Cells, colonies, biofilms, mats, EPS

Microorganisms generally occur as assemblages (colonies) of cells that may be monospecific, but, more often than not are plurispecies. Colonies are often linked by a film of polymers known as extracellular polymeric substances (EPS). Colonies coating a substrate in a two-dimensional manner are termed biofilms. Microbial mats are complex structures formed by layers of biofilms and may be microscopic to macroscopic in size, sometimes reaching dimensions of several square kilometers, for instance, on the floors of lagoons (e.g., Margulis et al., 1980). Although typically associated with the activity of photosynthetic microorganisms in shallow-water environments, microbial mats may also be constructed by non-photosynthetic microorganisms, such as the sulfur-oxidizers *Beggiatoa*, in deep-water habitats on the flanks of deep-sea hydrothermal vents and at hydrocarbon seeps (e.g., Kelley et al., 2005).

The structural components, cells, colonies, biofilms, mats, and EPS, may be preserved in rocks in a number of ways. Cells may leave organic walled impressions, mineral-coated or impregnated structures, or empty casts in a mineral precipitate. Biofilms and mats may also be preserved as organic impressions in sediments or mineralized structures.

Preservation of microbial structures

Organic walled structures: Cells walls can be preserved as organic impressions in fine-grained, anaerobic sediments (Javaux et al., 2001). The fixation of metals, such as Fe, on cell envelopes may retard lysis, thus contributing to the potential for preservation of cell walls (Ferris et al., 1988). While structures such as pollen spores are large enough to be visible in the rocks using light microscopy, individual microbial cells are often difficult to identify *in situ* in sediments because of their small size. Study of these organic remains is derived from palynological methods in which the detrital silicates encasing the cells are eliminated by acid-digestion of the rock. A major problem with this method is that microorganisms commonly colonize fractures in rocks, thus introducing younger contamination (e.g., Westall and Folk, 2003; Walsh and Westall, 2008). Such contamination led Pflug (1979) to identify eukaryotic yeast cells in a 3.8 Ga-old rock from Isua as *in situ* microfossils. This type of problem can be overcome by verifying the maturity of the kerogen by high-resolution TEM and Raman spectroscopy and/or by demonstrating chemical bonding between the organic molecules and the mineral matrix that indicates the syngenicity of the kerogen (Marshall et al., 2005; Derenne et al., 2008).

Mineralized microbial structures: The most common form of preservation of microbial structures is mineral fossilization. In this process, minerals bind to the organic surfaces of the cells/EPS in a passive reaction. The surfaces of microorganisms and EPS are very reactive, containing

ionized ligands to which mineral nuclei can attach themselves. The sorption reactions may take place via cation bridging, hydrogen bonding with functional groups such as carboxyls or hydroxyls, or by direct electrostatic fixation of the mineral to the functional groups (Lalonde et al., 2005). The attached nuclei then attract further nuclei, resulting in encrustation or permeation of the organic structure. The microbial surfaces and exopolymers therefore act as “mineralizing templates” (Konhauser, 2007). Depending upon the availability of the minerals in solution, the microorganisms may be completely entombed in a mineral precipitate. The type of mineral precipitated depends on the composition of the fluids and the redox conditions in the immediate environment of the microorganism. Many mineral phases can bind to microbial cell walls (Konhauser, 2007), including silica (Figure 1), carbonates (Ca, MgCa, Fe, Mn), metal oxides/hydroxides (Fe/Mn and magnetite), sulfates (Ca, Sr, Ba, Fe), sulfides (Fe, Ni, Pb, Zn, CuFe), phosphates (Ca), clays, and zeolites.

As noted above, cell wall composition and structure plays an important role in the fixation of metals because of the differential distribution of functional groups in different cell components. Mineral nucleation is similarly affected. Thus, Gram positive bacteria with their thick outer layer of peptidoglycan and the abundance of functional groups can be encased by a thick mineral crust, whereas the Gram negative bacteria with their thin layer of peptidoglycan sandwiched between an outer lipopolysaccharide layer and an inner phospholipid layer only fixed a thin, delicate crust (Westall, 1997). The latter author concluded that Gram negative cells therefore had less chance of being preserved in the rock record than Gram positive ones.

The cell walls of Archaea differ in their composition and structure to those of Bacteria and are also more variable. *Crenarchaeota* are characterized by a layer of paracrystalline proteins, the S-layer, which is loosely associated with the plasma membrane (NB: S-layers are also common around many species of Bacteria). The *Euryarchaeota* exhibit great variability in the composition of their cell walls, including a peptidoglycan-like component, pseudomurein. Experimental silicification of an Archaea having an S-layer, the hyperthermophile *Pyrococcus abyssi* showed that it produced a delicate silica crust, similar to that forming around Gram negative bacteria (Orange et al., 2009).

What is the fate of the organic components in a mineralized cell? Experimental fossilization shows that the macromolecules of the cell envelope may remain trapped in the mineral crust (Westall et al., 1995). The cytoplasmic space, on the other hand, may be empty after lysis, or, if lysis did not occur, it may contain balls of degraded macromolecules that can also nucleate minerals (in the process producing false nuclei, Westall et al., 1995). As noted above, the organic components of fossilized microbial structures may be preserved in anaerobic environments but they can be completely oxidized in

oxidizing environments. For example, the silicified remains of cyanobacteria in hot spring deposits from Yellowstone no longer contain any organic molecules (Cady and Farmer, 1996).

In order to be preserved in the rock record, the mineral-coated/permeated microbial structure needs to become encased in a mineral cement or by fine-grained sediments. Here, further diagenetic changes may take place, including changes in mineralogy (e.g., transformation of oxyhydroxides to oxides), replacement (complete or partial) of one mineral by another (e.g., silicification of carbonate mineralized remains), or dissolution. The final mineral or sediment-encased microbial fossils may exhibit different morphological preservation modes.

Artifacts: Abiological mineral precipitates can be notoriously confused with fossilized microorganisms. Many minerals may form simple spherical, oval, elongated, and even twisted morphologies. Silica spheres may occur in aggregates that look surprisingly like dividing microorganisms (e.g., Monty et al., 1991). Jones (2004) found that spherical silica aggregates nucleated onto a mucus thread in a siliceous hot spring forming filamentous structures that could possibly be mistaken for silica encrusted filaments. García-Ruiz et al. (2003) even showed that artificial mixed silica/organic precipitates could produce microbial-like morphologies (bacteriomorphs). However, these precipitates were not produced from naturally occurring solutions.

Examples of mineralized microbial structures: Microbial fossils occur throughout almost the whole of the rock record. The oldest known microfossils are found in silicified shallow-water volcanic sediments from the 3.5–3.3 Ga Barberton and Pilbara greenstone belts in which filaments, coccoidal and rod-shaped silicified microorganisms and associated EPS have been documented (Figure 1b) (Walsh, 1992; Westall et al., 2001, 2006a, b). [Older sediments from the 3.8 Ga-old Isua greenstone belt in Greenland are too highly metamorphosed to contain identifiable, syngenetic microfossils.] The very small size of the early Archaean microbial structures means that sophisticated instrumentation having high spatial and analytical resolution is necessary to observe and analyze them (Westall and Southam, 2006). Moreover, given the problem of establishing the biogenicity and syngeneticity of microbial remains in these ancient sediments, multiple lines of evidence are required, including morphological, chemical, and isotopic biosignatures. In this way, Westall et al. (2006a, b) documented multispecies colonies of probable chemolithotrophic microorganisms within 3.446 Ga-old mudflat sediments from the Pilbara and microbial mats on the surfaces of littoral sediments in a 3.334 Ga-old formation from Barberton. The small crystal lattice of silica results in excellent preservation of fine textural detail, such as cell surface wrinkles (Westall et al., 2006a). Silicified (permineralized) microfossils occur throughout geological time (Knoll, 1985). Proterozoic formations contain extremely well-preserved cyanobacterial

fossils, for instance (Green et al., 1989), and silicified microfossils have been documented from numerous Phanerozoic hot spring environments (Jones et al., 2001; Jones, 2004).

The oldest calcified microfossils are relatively poorly preserved benthic cyanobacteria from the 2.6 Ga Campbellrand Subgroup in South Africa (Kazmierczak and Altermann, 2002). Well-preserved calcified microfossils occur in younger Proterozoic formations, such as the Draken Formation, Svalbard (Knoll et al., 1993).

Microfossils preserved by other minerals, such as pyrite, occur through much of the geological record, the oldest such fossils occurring in the above-mentioned 3.2 Ga-old massive sulfide deposits from the Pilbara (Rasmussen, 2000) and younger fossils occurring in the Proterozoic, e.g., pyritized filaments in stromatolites from the Altyn Formation of Montana (White, 1974), or pyritized biofilms coating soft body parts (Canfeld and Raiswell, 1991). Phosphatized microfossils are known from the Phanerozoic, for example, phosphate coatings on cyanobacteria in Cambrian sediments from Australia (Southgate, 1986) or phosphatized microbial biofilms on the soft body parts of Eocene eucaryotes (Liebig et al., 1996).

Microbialites and microbial fabrics in rocks

The physical expressions of microorganisms and the products of their enzymatic and metabolic activities result in microbialite structures and textures that are characterized by a particular internal structure or texture. They include a wide range of macroscopic to microscopic phenomena, such as stromatolites, thrombolites, oncolites, biolaminites, and crusts (Figure 3). Macro- to micro-scale fabrics and textures related to the presence of microorganisms also include MISS (the MISS of Noffke et al., 2003), and microfossils (Burne and Moore, 1987; Monty et al., 1995; Riding and Awramik, 2000). Microbialites and microbial fabrics are found in rocks throughout the geological record with the oldest stromatolites occurring in 3.5–3.3 Ga-old formations in the Pilbara of Australia and in Barberton, South Africa (Lowe, 1980; Walter, 1983; Byerly et al., 1986; Hofmann et al., 1999; Allwood et al., 2006). The biogenic origin of the early Archaean stromatolites has been challenged by Lowe (1994) and Lindsay et al. (2005) but Riding (2008) suggests that some of the Precambrian stromatolites may be mixtures of microbial and abiogenic, stromatolite-like fabrics. The large and diverse stromatolites characteristic of the Proterozoic declined in importance throughout the latest Precambrian to Cambrian times and, from the early Cambrian onwards, microbialite structures are dominated by microbial mounds formed by non-stromatolitic calcifying microbes (e.g., cyanobacteria, Monty, 1995). Microbial mounds are well-developed throughout the geological record spanning from the Proterozoic to the Recent in both shallow- and deep-water settings and are considered to be a significant expression of the history of Earth's microbial life (Figure 2) (Monty, 1995). Both stromatolites and

microbial mounds are characterized by the activity of microbes which calcify, trap, and bind sediments, forming delicate and persistent microstructures rich in micrite (microcrystalline calcite) and organomicrite. Microbially generated mounds and microbialites formed in shallow-water environments mainly involve photosynthetic/phototrophic and heterotrophic microbes. In deeper waters, however, chemosynthetic microbes are associated with hydrocarbon seeps and hydrothermal-related mound deposits (Peckmann and Thiel, 2004). Deep-water stromatolitic fabrics and crusts have been described from hydrocarbon seeps on the Aleutian accretionary margin as a product of methane-consuming Archaea (Greinert et al., 2002).

The most common microbially induced fabrics from carbonate rocks are clotted and peloidal fabrics (Burne and Moore, 1987; Shapiro, 2000; Flugel, 2004). These fabrics consist of spherical-to-elliptical microscopic aggregates of microcrystalline clots or peloids (Figure 5a) (e.g., calcite, aragonite), cemented by carbonate and/or sediments (MacIntyre, 1985; Shapiro, 2000). Fenestral and stromatactis fabrics from organic-rich sedimentary deposits (Figure 5b), such as microbial mounds or geothermal springs (e.g., travertine), are microbiological in origin (Flugel, 2004). Encrustations, concretions, and coatings are generally microbial products that contain a record (morphological, geochemical, and/or isotopic) in their sedimentary phases of the biochemical processes involved in their genesis (Raiswell and Fisher, 2000; Kiriakoulakis et al., 2000). For instance, Fe-Mn coatings and pyritiferous carbonate nodules are considered to be microbial fabrics (Peckmann and Thiel, 2004).

Microbially induced sedimentary structures (MISS) are formed by the rhythmic alternation of photosynthetic microbial mats and sediments in mudflat environments (Noffke, 2008). MISS are widespread in the geological record and have also been identified in sediments 3.2 Ga-old from South Africa (Noffke et al., 2003).

Banded iron formations (BIFs) occur throughout the rock record from 3.8 Ga onwards (BIFs occur in the Isua greenstone belt in Greenland). The influence of microorganisms on the formation of these laminated accumulations of iron oxides and chert is the subject of much controversy. Photochemical oxidation of ferric iron of hydrothermal origin is one explanation (Cairns-Smith, 1978) but other biological controls have also been suggested, such as oxidation by oxygenic photosynthesizers (Cloud, 1965), or simple sorption of Fe^{2+} onto microbial cell surfaces to catalyze a basically abiological precipitation process (Konhauser, 2000), or the precipitation of Fe oxides by Fe oxidizing microorganisms (Posth et al., 2008).

Relevance of biosignatures and their astrobiological implications

We have seen above that a number of the biosignatures described can be imitated by abiological processes

Biosignatures in Rocks, Figure 5 Micrometer-scale biosignatures in rocks. Transmitted light photomicrographs of petrographic thin sections. (a) Continuous and planar laminations of stromatolite structures from the Devonian Hollard Mound (Morocco). The arrows indicate the spar-filled cavities generating fenestral fabrics. (b) Detail from (a) showing a lamina of fine gray micrite (m) that locally consists of microbially produced peloids (arrows). Scale bars: (a) = 5 mm; (b) = 200 μ m. (Images reprinted with permission from Cavalazzi, 2007, and Cavalazzi et al., 2007).

resulting in significant controversy. These are serious limitations when searching for the first traces of life on Earth or for biosignatures on other planets. How can nonliving molecules be distinguished from very primitive living cells – and in the fossilized form? A carbon isotope signature on its own is not sufficient because it could be either abiogenic or biogenic in origin. A collection of simple-shaped minerals, even joined together with compromised boundaries, could represent abiogenic precipitates or possibly a fossilized microbial colony. Identification of biosignatures in ancient terrestrial or extraterrestrial materials therefore needs to be based on a combination of structural, chemical, and isotopic traces that are related to the three main characteristics of living organisms: their physical structures, the chemical components of the structures, and their metabolic or living processes (Westall and Southam, 2006; Westall, 2008). Another aspect to take

into account is the fact that living organisms by their very existence and metabolism interact with and influence their immediate environment.

On a biotic world where the context of structure, fabric, and composition are well-constrained, certain characteristics, such as element enrichment, mineral composition, shape, and size can be used as complementary evidence for the existence of living organisms. Can these characteristics be used on a world where the existence of life forms is uncertain, for instance on the primitive Earth or Mars? Prebiotic molecules of mostly extraterrestrial origin, characterized by a wide range in composition and structure, including simple amino acids, polycyclic acidic hydrocarbons (PAHs), thiophenes, fullerenes etc. (Cronin, 1998), abounded on these worlds (Maurette et al., 2000). Could prebiotic organic macromolecules scavenge elements from the environment in the same way as biomolecules and, if so, would some elements be preferentially fixed? These macromolecules have very few of the functional groups that characterize biogenic molecules, and it is therefore unlikely that they will be able to induce significant metal fixation. Thus, element concentration and distribution in potentially biogenic materials (organic or mineralized organics) could be considered as a useful complementary biosignature when associated with other types of biosignatures. Could prebiotic organic molecules induce mineral precipitation? Again this is unlikely since biominerals precipitate because of changes in the environment caused by the excretion of metabolic waste products, or enzymatic mediated changes in the redox state, or the presence of a charged cell surface that attracts mineral nucleation, conditions that are not met by prebiotic molecules. On the other hand, the physical presence of prebiotic molecular matter in an environment where minerals are being precipitated abiotically from supersaturated solutions (saline ponds, hot springs, the early, silica-saturated oceans) could eventually have an influence on the size and shape of minerals because of alteration in the stability of the crystal surfaces (cf. Mann et al., 1993; Albeck et al., 1996).

Once the biogenicity and syngenicity of the different biosignatures in a rock have been established, how are they to be interpreted? What do they tell us about the community of microorganisms that lived in a particular environment? Are all the original microorganisms in the community preserved? This is particularly relevant because not all microorganisms can be fossilized. For instance, Orange et al. (2009) noted that, although two species of thermophilic Archaea, *Pyrococcus abyssi* and *Methanocaldococcus janaschii* had similar cell wall structures and compositions, the former could be experimentally silicified whereas the latter naturally lysed before mineral nuclei could fix to the cell walls.

Another aspect of the study of biosignatures is the importance of observation and analysis at the scale of the microorganisms (Westall and Southam, 2006; Westall, 2008, 2009). Many fossilized microorganisms are very small and cannot readily be distinguished from abiogenic

mineral accumulations at the optical microscope scale. They need to be studied using higher-resolution electronic microscopes. The question of scale is also pertinent to analysis of chemical or isotopic signatures. What information about the microbial community is provided by isotope measurements made on kerogen extracted from the bulk rock when the rock may contain traces of different microbial communities at the micrometer scale? The microbial communities (colonies, biofilms, and mats) may, themselves, consist of multiple species, thus, resulting in additional mixture of the isotopic signature. To complicate matters even further, specific components of an individual cell may have different isotopic signatures. For example, van de Meer et al. (2000) note that the carbon isotope composition of the lipids of *Chloroflexus aurantiacus* differ from the bulk isotopic composition of the cells. This means that isotope measurements made even *in situ* (e.g., with a spot size of ~50 μm , van Zuilen et al., 2007) need to be interpreted with caution.

Conclusion

While it is clear that the study of biosignatures in rocks is not without difficulties, these can be overcome by combining signatures of the different aspects of living organisms, i.e., structural, chemical, and isotopic traces, as well as evidence for the interaction of living organisms with the environment. Further investigation of the microbial communities that produced the biosignatures needs to be undertaken at the microbial scale in order to obtain relevant information about the types of organisms and their metabolic activities. This is a challenge for spatial and analytical resolution but it is this level of detail that is necessary for disentangling the bulk biosignatures from those produced by the individual microorganisms and for better understanding the complexity of past communities.

BIOSILICIFICATION

The biological formation of opal-like amorphous hydrated silica. This phenomenon occurs on a globally vast scale in a wide variety of organisms, including protists, radiolarian, foraminifera, sponges, molluscs, brachiopods, copepods, ascidians, diatoms, and higher plants. See entries “[Silica Biomineralization, Sponges](#)”, “[Microbial Silicification – Bacteria \(or Passive\)](#)” and “[Microbial Biomineralization](#)” for further reading.

BLACK SHALES

Wolfgang Oschmann
 University of Frankfurt, Frankfurt, Germany

Definition

Most modern and ancient aquatic (marine, brackish, and lacustrine) environments were sufficiently oxygenated to permit colonization by numerous benthic, planktic, and nectic organisms. Due to excess oxygen the biologically produced organic matter is rapidly degraded. The sediments formed thereby exhibit only very low amounts of organic matter.

In contrast, very high rates of primary production and/or stagnant water bodies result in black shale sedimentation, which is associated with oxygen depletion or even lack of oxygen within the substrate and to some extent also within the water column. Degradation of organic matter is incomplete, partly by anaerobic bacteria, causing strong enrichment of organic matter in sediments. Black shales therefore commonly exhibit excellent preservation of organic molecules and mineralized soft tissues and hard parts of organisms.

The importance of black shales for scientists and the society are twofold. Black shales serve as source rocks for fossil fuels (oil and gas), which cover most of the energy needs of modern societies, and due to excellent preservation they provide particular sites for palaeontological studies.

Sedimentary characteristics of black shales

Black shales sediments in common are dark gray to black in color and are characterized by microlaminations, which may vary from distinct to blurred. The lamination is caused by quiet depositional conditions and the scarcity or lack of bioturbation. In many cases, the lamina were formed by alignments of fecal pellets ([Figure 1a](#)), which rained down in great numbers from surface waters. The
